Rice's Method for Preparing Acidophilus Milk in the Home. Rice⁵³ reported a method for preparation of acidophilus milk on a small scale. The milk should be free from those bacteria which naturally occur in fresh milk. This can be obtained by boiling market milk for a long time, or unsweetened evaporated milk may be used. The evaporated milk is particularly desirable since it is always ready for use, and it is sterile. The *Lactobacillus acidophilus* culture may be secured at drug stores. This organism grows best at 32.2°C.(90°F.) to 40.6°C.(105°F.) although it grows to considerable extent at room temperature. The procedure requires the use of a thermos bottle which has been thoroughly sterilized. Wipe the top of a one-pound can of evaporated milk free from dust and pour boiling water over it. Open the can and pour contents into a pan that has been scalded. Fill the can with boiling water and pour into the evaporated milk. Cool the mixture to about 105°F. Add two or three ounces of commercial *Lactobacillus acidophilus* culture, mix, and transfer to the thermos bottle. Cork and let stand for 24 hours, or until the milk has a pleasantly sour taste. Transfer to a clean milk bottle and place in the refrigerator. Succeeding cultures of acidophilus are prepared

52. Hughens. 1924. U. S. Naval Med. Bull. 21, 548-549.

53. Rice. 1928. Amer. J. Pub. Health 18, 1105.

by using about a teacupful of milk culture previously made to inoculate diluted evaporated milk for the next turn. Thirteen to 17 hours are quite sufficient for succeeding cultures. Milk kept in a refrigerator must be used within 48 hours because the organisms rapidly die out at such low temperatures. Typical acidophilus milk has a fine grained curd and is not "stringy" as is that produced by *Lactobacillus bulgaricus*. The fact that the commercial culture is much less active than the prepared milk culture used for inoculation shows how much greater must be the therapeutic value of the latter.

Knaysi's⁵⁴ Method for Preparing Acidophilus Milk. Knaysi stated that this method overcame some of the difficulties inherent in other methods. He believed that the great problem was elimination of rapidly developing sporulating bacteria. His method consists in incubating skimmed milk at 37 to 47°C.(98.6 to 116.6°F.) for two and one-half to three hours, heating to as near the boiling point as possible for 30 minutes, followed by prompt cooling to 37 to 40°C.(98.6° to 104°F.). The milk is then inoculated with a culture of *Lactobacillus acidophilus* and allowed to coagulate.

Storage of Acidophilus Milk. Biological products are usually stored in the refrigerator. Acidophilus milk is no exception. Kopeloff⁴² made daily determinations of the number of viable cells in milk kept in a refrigerator at 9°C.(48.2°F.). There was a 50-per cent reduction in one day, a 75-per cent reduction in two days, and 90 per cent in three days. Kopeloff, therefore, believed that acidophilus milk should be stored at room temperature instead of in an icebox. This would not result in such a rapid decrease in the number of viable cells. Different conditions of storage might easily explain the various results which have been secured in the examination of these products. Black,⁵⁵ on the other hand, stated that *Lactobacillus acidophilus* milk cultures may be stored at refrigerator temperatures for several days without deterioration in the number of living cells. Less reduction in numbers occurred at 9°C. or even 0°C.(32°F.) than occurred at 37°C.(98.6°F.). Black believed that cultured milk could be held at 4.4°C.(40°F.), or below, for several days without materially affecting the content of viable cells. All strains with which Black worked acted in the same manner. Kulp,⁵⁶ in general, confirmed Black's work. To insure satisfactory viability for two days to a week, Kulp suggested a storage temperature of 5°C.(41°F.), provided the acidity was not above .65 per cent. To insure viability for a longer time, Kulp stated that the number of foreign bacteria must always remain at a negligible figure; rigid precaution against excessive acidity must be observed; the storage temperature should range between 12 and 16°C.(53.6 and 60.8°F.), the optimum viability temperature for *Lactobacillus acidophilus* in milk being 16°C. when the initial acidity is .65 per cent. Kopeloff, Etchells, and Kopeloff⁵⁷ stored acidophilus milk prepared with an R and an S strain of *Lactobacillus acidophilus* with initial acidities of six-tenths and one per cent at 4 and 20°C.(39.2 and 68°F.). The viability of these two strains differed. The R strain, the only one of proved therapeutic value, lost its viability more rapidly at 4°C. than at 20°C. The original count was diminished approximately 90 per cent after three days in the icebox. The S strain lost its viability less rapidly but storage in the icebox was more detrimental

than at room temperature. It is recommended that acidophilus milk be kept in a cool place, but not in an icebox.

Attempts have been made to incorporate *Lactobacillus acidophilus* in various dairy products. In one of them Prouty and Bendixen⁵⁸ incorporated the organism in sherbet and determined its ability to survive. The number of viable cells after five days' storage at $-17^{\circ}\text{C}.$ ($1.40^{\circ}\text{F}.$) was a few million per ml. with one culture, but several hundred million with three others. Higher titratable acidity caused more rapid decrease in living organisms, but sugar concentration seemed to have no effect. Prouty and Bendixen stated that sherbet with high numbers of *Lactobacillus acidophilus* could be prepared by keeping acidity below one per cent and using resistant strains.

Other Lactobacillus Acidophilus Preparations. Effort has been made to incorporate *Lactobacillus acidophilus* in materials other than milk. Rettger, in whose laboratories acidophilus milk was originated, believed that milk was the best medium in which to distribute the organism. One of the first to sound a note of warning in the use of various products containing *Lactobacillus acidophilus* was Bass.⁵⁹ He considered it advisable to warn against making the same kind of mistake with *Lactobacillus acidophilus* that was made with *Lactobacillus bulgaricus*. Enthusiastic workers were reporting most striking therapeutic results from the administration of broth cultures of *Lactobacillus acidophilus* in teaspoonful doses, only a small fraction of the amount of culture that others had found necessary to change noticeably the intestinal flora. Commercial interests placed on the market *Lactobacillus acidophilus* in the form of tablets, capsules, and liquids. Bass examined some of these preparations to determine the number of viable *Lactobacillus acidophilus* contained therein. In the instance of tablets, none of those examined was found to contain as many as 1,000 viable bacteria of any kind per tablet. If it should be granted that all the viable bacteria present were *Lactobacillus acidophilus*, it would take more than 1,000,000,000 tablets, or more than 20 tons, to contain as many bacilli as are contained in 1,000 ml., or the usual daily dose, of acidophilus milk, the quantity found, by most investigators at least to be necessary to transform the flora. Bacteria were more numerous in the commercial liquid cultures examined. If they were all *Lactobacillus acidophilus*, a patient would have to drink seven or eight gallons daily to get as many as he would in 1,000 ml. of the acidophilus milk culture. Only fresh cultures produced according to the proper bacteriological methods should be used. The Council on Pharmacy and Chemistry of the American Medical Association⁶⁰ attempted to take a conservative position on these products. This bureau has considered acidophilus milk and broth cultures and concentrates of *Lactobacillus acidophilus* not acceptable unless the number of viable organisms is clearly stated on the package. This is not enough. The number of cells must be known to survive when the consumer purchases

58. Prouty and Bendixen. 1932. J. Dairy Sci. 15, 413-419.

the package. Certain other products are not accepted unless adequate evidence that they will induce implantation is presented. Results of an extensive study of these products were reported by James⁶³ from the laboratories of the Bureau of Chemistry. James' results would indicate that some of these products were worthless. The milk cultures showed the greatest number of viable cells, the whey cultures next, and the solid cultures the lowest. In some cases, James was unable to find *Lactobacillus acidophilus*. He examined 107 samples of which only 15 were sufficiently pure or had a sufficient number of viable cells to have possible value. Examination of tables in James' paper showed counts of milk cultures on whey galactose agar which varied from 450,000 to 4,750,000,000 per ml. Broth cultures showed a variation between 0 and 250,000,000. Cheplin, Post, and Wiseman⁶¹ also claimed that the tablets of *Lactobacillus acidophilus* were useless for transforming the flora. Kopeloff, Cohen, and Beerman⁶² observed that only five of the eight products examined gave any information on the label as to the number of viable organisms. But three of these fulfilled their claims. Three of the specimens examined contained *Lactobacillus acidophilus* as the predominating organism. Only one product contained the specified number of living cells identical with known stock cultures of *Lactobacillus acidophilus*. These results bear out the findings of James⁶³ and Bass.⁵⁹ Kopeloff and his colleagues recommended that the labels carry more complete information about the product.

James' ⁶³ Method for Examining *Lactobacillus acidophilus* and *Bulgaricus* Preparations. James used the following methods in his work on commercial preparations:

1. Liquid (broth or milk) cultures:

(a) One milliliter of the culture was inoculated directly into each of two tubes containing 20 ml. of litmus milk. The largest amount of culture inoculated was one ml.

(b) One milliliter of the culture was added to nine ml. of sterile water, and one ml. of this dilution was inoculated into the first set of plates. Different platings were made in triplicate with dilutions to 1:100,000,000. The largest amount of culture plated was .1 ml.

2. Solid (tablet or powder) preparations:

(a) Three tablets (or the powder from three capsules) were dissolved in 30 ml. of sterile water.

(b) One milliliter of this dilution was then added to each of two tubes containing 20 ml. of litmus milk. The largest amount of culture inoculated was .1 ml.

(c) One milliliter of the dilution used in a was seeded in the first set of plates. Higher dilutions were then plated. All platings were made in triplicate. The largest amount of culture plated was .1 ml.

3. Semisolid or jelly cultures:

(a) Cultures liquefying at 40°C.(104°F.). These usually had a consistency resembling that of petrolatum. A sterile glass tube (inverted 10 ml. pipette with full size opening) was thrust to the bottom of the jelly and the subsample thus obtained blown into a sterile tube. The tube and subsample were placed in a 40°C.(104°F.) bath, where the jelly was melted and could be handled with a previously warmed pipette. After thorough mixing, one ml. was transferred to nine ml. of warmed sterile water and vigorously shaken.

(b) Cultures not liquefying at 40°C.(104°F.). These consisted of solidified agar in which bacteria were suspended. The agar was molded in cubes, each wrapped sep-

62. Kopeloff, Cohen, and Beerman. 1928. J. Amer. Med. Assoc. 91, 1187-1192.

63. James. 1927. J. Amer. Med. Assoc. 89, 89-92.

arately. One cube being considered as one dose, it was selected as the unit. Each cube was thoroughly ground in a sterile mortar, after which 10 ml. of sterile water were slowly added, with continued grinding until an even suspension was obtained. Sterile dry sand was used when necessary, but sparingly in order to avoid rupturing the bacteria.

Kopeloff, Cohen, and Beerman's⁶² Method for Examining *Lactobacillus acidophilus* Preparations. The following data were recorded: name, date received, date of examination, date of manufacture, date of expiration, number of acidophilus bacilli guaranteed, character of vehicle, color, taste, consistency, acidity (titrated with tenth-normal sodium hydroxide) and Gram stain (Kopeloff and Beerman modification).

The determination of the number of viable acidophilus bacilli was made by plating all milk samples on the same batch of whey agar and casein digest agar. Aqueous suspensions were plated on meat infusion (instead of whey) agar and casein digest agar. The concentration of agar in all mediums was 1.2 per cent and the pH from 6.8 to 7.0. One per cent lactose was always added. The plates were incubated at 37°C. (98.6°F.) for three days ordinarily, and a parallel series was incubated in the presence of five to 10 per cent carbon dioxide gas.

Before plating, the following dilutions were made: 10 milliliters of the original sample were added to 90 ml. of physiological sodium chloride solution, making a dilution of 1:10. Subsequent dilutions of 1:1,000, 1:100,000 and 1:1,000,000 were made. One milliliter of dilutions 1:10 and 1:1,000 were plated in quadruplicate, while dilutions of 1:100,000 and 1:1,000,000 were plated in sextuplicate. Then one-half of the plates were incubated atmospherically at 37°C. (98.6°F.) and the other half in five to 10 per cent of carbon dioxide. A preliminary examination of atmospherically incubated plates was made at the end of 24 hours to determine the number of contaminants present. Control plates were always included. At the end of three days' incubation, all plates were counted with a magnifying lens and the numbers of acidophilus bacilli and contaminants appearing on the plates from the two highest dilutions were recorded.

THERAPEUTIC USE OF ACIDOPHILUS MILK

Considerable success has been attained with the acidophilus preparations, especially acidophilus milk. Rettger and Cheplin¹⁶ reported interesting results following administration of these preparations.

Psychoses. In general Kopeloff and Beerman⁶⁴ were able to show improvement over their original condition following administration of acidophilus milk to psychotic individuals. The constipated cases were greatly benefited and the non-constipated had a greater number of normal defecations. Julianelle and Ebaugh⁶⁵ recommended acidophilus milk for psychotic patients because it tended to better physical well-being. They observed no change in the psychoses. About the same conclusions were reached by Brown and Borden.⁶⁶

Constipation. This is one of the first ailments to be treated with acidophilus therapy. Gompertz,⁶⁷ Cheplin and Wiseman⁶⁸ and Mizell⁶⁹ reported fairly prompt response. Rettger and Cheplin¹⁶ used two obstinate cases of constipation which responded readily to treatment. Cheplin, Fulmer, and Barney,⁷⁰ Kopeloff and Cheney,³⁷ and Cheplin⁷¹ published further conclusions.

The subject is somewhat confused by statements by Smith and Kulp,⁷² and Kast, Short, and Croll,⁷³ that if urinary indican is accepted as an index of intestinal putrefaction, acidophilus therapy has no effect. Some patients showed increased amounts of indican and phenols in their urine during treatment. Kahn,⁷⁴ however, reported the opposite. Segal's⁷⁵ conclusions agree with those of Smith and Kulp,⁷² while Fisher's⁷⁶ agree with Kahn's. It is difficult, therefore, to reach conclusions on the subject. Later work by Weinstein *et al.*⁷⁷ reported some success with acidophilus milk in one-quart quantities daily. The cultures used for preparation of the milk were known to possess high viability. In some cases the organism remained in the intestines for 12 to 16 weeks after the milk treatment had been discontinued. Most favorable results were said to be secured by using the milk over long periods.

Diarrhea. Cheplin and Rettger¹⁶ reported improvement in patients suffering from diarrhea following administration of acidophilus milk. Patients treated by Gompertz⁶⁷ developed formed stools after *Lactobacillus acidophilus* had been implanted.

Epilepsy. Since the gastrointestinal tract has been under suspicion in epilepsy, Kopeloff, Lonergan, and Beerman⁷⁸ fed acidophilus milk to epileptics to determine any effect this might have on the number of convulsions. Fifteen epileptics were used in one experiment. They were given one liter of acidophilus milk a day for 42 days with beneficial results. Ingestion of sterile milk did not influence the number of convulsions. Neither did the ingestion of six grams of kaolin daily for one month. But when the same quantity of *Lactobacillus acidophilus* milk, one liter reinforced with 300 grams of lactose, was administered for two months, there was a striking reduction in the number of convulsions in five patients. Three patients remained the same and one showed a slight increase in the number of convulsions. In the two-month period following administration of *Lactobacillus acidophilus* milk the patients had an increased number of convulsions. It appeared therefore, that the treatment was not sufficiently prolonged to confer permanent benefit. The work of Lynch⁷⁹ did not confirm the beneficial effects of acidophilus therapy in epilepsy. The number of defecations was increased whether the bacteria were given in milk or blocks.

Typhoid and Paratyphoid Carriers. Smith⁸⁰ gave *Lactobacillus acidophilus* to typhoid and paratyphoid carriers; after transformation, from 80 to 90 per cent of the flora became *Lactobacillus acidophilus*. Excretion of *Eberthella typhosa* and the paratyphoids was not influenced by acidophilus milk administration.

Lactobacillus bifidus (Bacillus bifidus). This organism was discovered by Tissier and named *Bacillus bifidus*. It is a normal intestinal form and very pleomorphic. In most of the cultures Y and T forms are common. Kendall and Haner⁸¹ stated that variants of the type are common as determined by morphological characteristics and sugar-fermenting powers. They found the organism to be more pleomorphic in artificial cultures than

in the feces. Adam ⁸² believed that the peculiarities of the cells of *Lactobacillus bifidus* were due to their metabolism. Kling ⁸³ observed an antagonistic action of *Lactobacillus bifidus* on a number of intestinal forms, such as *Escherichia coli*, *Aerobacter aerogenes*, and *Staphylococcus aureus*. This action could not be explained on the basis of heat labile bactericidal substances, such as those found by Eijkmann and called "autotoxins." According to Brown and Bosworth ⁸⁴ the stools of normal breast-fed infants showed a complete dominance of *Lactobacillus bifidus*. When cow's milk is fed, the stools show larger numbers of cocci and Gram-negative bacilli than are usually found in stools of breast-fed babies. These organisms may persist for as long as four weeks. With regard to the source of *Lactobacillus bifidus* Brown and Bosworth stated that "the bifidus organisms which are present in or on the mother's nipple are an important source of the bifidus organisms found in the nursling's intestines." Lauter ⁸⁵ also stated that intestinal infection of the infant is by mouth. *Lactobacillus bifidus* was said to appear in the stool about two and one-half days after birth. About the same conclusions were reached by Boventor ⁸⁶ who stated that this organism was the predominating one in stools of newborn babies. He also gave instructions for cultivating the organism. Weiss and Rettger ⁸⁷ stated that *Lactobacillus bifidus* may constitute from 90 to 95 per cent of the intestinal flora of breast-fed infants. It remains the predominating organism as long as breast milk is the sole diet.

The taxonomic relationships of this organism have been a matter of discussion among bacteriologists for some time. It has been placed in one genus and another until now it seems to be fairly firmly established as a member of the genus *Lactobacillus*. Weiss and Rettger ⁸⁷ were of the opinion that *Lactobacillus bifidus* should be considered a variant of *Lactobacillus acidophilus*. Only slight differences between the two organisms were observed and these could be accounted for by normal variation within the species or type. Rettger and Weiss ⁸⁸ agreed with Eggerth ⁸⁹ that the Gram-positive, nonsporeforming anaerobes of the human intestine do not belong to the group *Bacteroides* and that this name should be retained for the Gram-negative organisms.

Buttermilk. This is one of the commonest fermented milks and is usually prepared during the churning of sour cream for butter in which process it is a by-product. Owing to the great interest in artificial or cultured buttermilks these products have appeared on the market. Popular discussions have done much to stimulate interest in fermented milks. Not enough buttermilk could be produced in cities to supply the demand. Consequently, dairies are preparing artificially inoculated and soured milk. Such fermented milks often have a better flavor than buttermilk. Some

buttermilk may possess an undesirable flavor, owing to the presence of foreign bacteria. The Secretary of Agriculture promulgated the following definition of buttermilk in Food Inspection Decision No. 210, issued April, 1927:

Cultured buttermilk is the product obtained by souring pasteurized skimmed, or partially skimmed milk by means of a suitable culture of lactic acid bacteria. It contains not less than eight and five-tenth per cent (8.5%) of milk solids not fat.

The Milk Ordinance and Code of the United States Public Health Service (1939) defines it as follows:

F. Buttermilk. Buttermilk is a product resulting from the churning of milk or cream, or from the souring or treatment by a lactic acid or other culture of milk, skimmed milk, reconstituted skimmed milk, evaporated or condensed milk or skimmed milk, or milk or skimmed-milk powder. It contains not less than eight per cent of milk solids not fat."

The microbiology of buttermilk is probably not greatly different from that of butter. Many of the organisms originally in the milk or added in the starter probably appear in the buttermilk.

Reid's⁹⁰ Method for Making Buttermilk Beverages. Reid conducted the following investigations at the University of Missouri to produce buttermilk drinks which will not whey off. Five one-pint samples of milk with an acidity of .16 per cent were heated to 87.8°C.(190°F.) for 40 minutes to destroy all bacteria present, cooled to 21.1°C.(70°F.), inoculated with one per cent of a culture of *Streptococcus lacticus* and *Bacterium acidi lactici*, and held until coagulation started, which took place in seven hours. They were then cooled to 5.6°C.(42°F.), held until the next day, and examined. Samples were also prepared in the same manner as above, except that before heating gelatin was added to four of them in the following amounts: .25, .55, .75, and one per cent, respectively. These samples were scored the next day and again after aging six days. After standing one day, the check sample had an acidity of .7 per cent and was free from gas and whey. Before shaking, the body was medium firm and the aroma medium full, clean, and pleasant. After shaking, the body was smooth, velvety, and fairly firm and the flavor clean and desirable. After standing six days, there was a decided wheying off, the body was weak, the aroma improved, and the flavor unchanged. Addition of gelatin prevented wheying off but had no effect on flavor or aroma. Amounts of .1 and .25 per cent gelatin gave best results.

Busa. This is a fermented milk prepared in Turkestan. It contains, according to Chekan,⁹¹ up to .78 per cent of lactic acid and up to 7.1 per cent of alcohol by weight. Chekan stated that the alcoholic fermentation of rice was induced by *Saccharomyces busae asiaticae* and a bacterium named *Bacterium busae asiaticae*. The yeast grows better in the presence of organic matter. Chekan stated that it ferments maltose best; sucrose, dextrose, levulose, lactose, and dextrin next best; inulin very slightly; and mannitol, arabinose, and starch not at all. The optimum pH for growth is 6.4 to 6.7. The lactic acid bacillus grows better when in root extract agar and when stabbed. The maximum acid production is 1.1 per cent. It ferments dextrose, galactose, maltose, sucrose, levulose, lactose, and arabinose strongly and mannitol, dextrin, and starch weakly. The best sources of nitrogen are peptone, phaseolin, gelatin, and alanine. The optimum pH is 6.7.

91. Chekan. 1922. Centbl. Bakt., Pt. 2, 78, 74-93.

Cieddu. This is a fermented milk made in Italy and, according to Rosini,⁹² corresponds to kumiss, kefir, and a few other fermented milks. He stated that it was antagonistic to pathogenic microorganisms in the intestines. Samarini⁹³ reported that bacteriological examination of fresh cieddu (Sardinian fermented milk) showed the presence of only two forms of microorganisms, one a variety of *Bacterium lactis acidii* and the other a variety of *Bacillus casei* of Freudenreich.

Dadhi. Dadhi is a product made in India by curdling milk through the growth of certain lactic acid-forming bacteria. It is prepared by heating fresh milk to boiling, allowing it to cool to about 36.7 to 37.8°C. (98 to 100°F.), and adding a small quantity of dadhi from an earlier batch. Upon standing overnight in a covered container a smooth, homogeneous curd with an acid taste is produced. Examination of dadhi films by Ram-Ayyar⁹⁴ showed the presence of very long rods, short rods joined in pairs, cocci, and yeast cells. In summer, 24 hours after inoculation, dadhi contains long rods (*Streptothrix dadhi*) almost exclusively, the acidity of the product at the end of that time being one to 1.4 per cent, calculated as lactic acid, when the milk is kept at 36.7°C. (98°F.). In winter, the chief agent responsible for curdling is the short, rod-type organism which grows well at 20°C. (68°F.) and produces .5 to .7 per cent acid in 24 hours. The product of low-temperature fermentation is known as "sweet dadhi." A nonsporeforming yeast of the *Torula* type is always associated with both types of lactic acid organisms in dadhi. This yeast grows only in curdled milk of acid reaction and consumes the lactic acid produced by other organisms. It grows well in media containing sucrose or glucose and does not produce alcohol from any sugars. Lactic acid-forming bacteria live longer when associated with this yeast because of its ability to prevent the accumulation of toxic quantities of acid.

Kefir. This is one of the best-known fermented milks prepared by the inhabitants of certain of the Balkan countries. Little if anything is known about its origin. Many investigations have been carried out on it to determine the causes of the fermentation and whether it is possible to prepare it by pure-culture inoculation. Among the earliest of these was that of Kern.⁹⁵ The first complete investigation of the fermenting agents of kefir was made by Freudenreich,⁹⁶ the eminent Swiss dairy bacteriologist. He found a yeast, *Saccharomyces kefir*, which lived symbiotically with two bacteria, *Dispora caucasica* and *Streptococcus A*. *Saccharomyces kefir* when isolated by itself did not act on lactose. Jandini⁹⁷ also found a yeast and several bacteria in the fermenting organisms of kefir. *Torula kefir* was isolated by Beijerinck,⁹⁸ and Nikolajewa⁹⁹ believed that a *Torula* which fermented lactose, sucrose, and dextrose was essential to formation

of good kefir. *Torula ellipsoidea* was also isolated. *Bacterium caucasicum*, the organism mentioned by Beijerinck, was also observed. Essaulow¹⁰⁰ isolated, from kefir grains of various origins, a *Saccharomyces*, *Bacillus acidi lactici*, and *Bacillus subtilis* in every case. Other microorganisms isolated from kefir grains were believed to be contaminants and to cause trouble in the fermentation. Neither of these three microorganisms alone can produce anything like kefir. *Bacillus subtilis* did not appear to have any part in preparation of kefir grains; it was believed to produce a network which supported the other two microorganisms. Alcohol, carbon dioxide, and peptone were recognized in kefir. Work of this nature was carried on also by Kuntze.¹⁰¹ Two sporeforming species belonging to the butyric acid-producing group were regularly found. One was believed to be a variety of *Bacillus esterificans* while the other was designated *Bacillus kefir*. According to Kuntze, the characteristic kefir fermentation is due more to these butyric acid fermentations than to lactic acid-producing fermentations or to activities of yeasts. A more heterogeneous flora of microorganisms was found in kefir by Kornblum.¹⁰² They were grouped as follows:

1. *Streptococcus lacticus* Kruse, of which three types were isolated.
2. Nonsporeforming oval yeasts resembling *Saccharomyces kefir* and *Torula lactis* Adametz; three types of yeasts were also isolated.
3. *Oidium lactis*, a harmful contaminant of kefir which produces a rancid, bitter taste in old cultures.

In none of the kefir-milks examined could Kornblum find the microorganisms mentioned above reported by earlier workers. The mixed flora of the fermenting agents of kefir was again brought out in the results of investigations by Starygina and Khaldina¹⁰³ who believed the main elements of the microflora of kefir to be the lactic acid-producing Streptococci, lactic acid-producing rods, yeasts, and a small number of peptonizing bacteria. The latter are apparently quite important. Samtsevich¹⁰⁴ found them to be important. They produce a good consistency and flavor. A few investigators have studied the possibility of using pure cultures for making kefir. Kornblum¹⁰² secured satisfactory results with the microorganisms which he isolated without *Bacillus caucasicus*. By varying the amount of the different organisms kefir of various qualities could be produced. Starygina and Khaldina¹⁰³ also found pure cultures possible. A composite starter was prepared also by Palladina, Krotova, and Maejukewitsch¹⁰⁵ consisting of various bacteria and yeasts.

Kumiss (Kumys). Preparation of this fermented milk has been described in some detail by Rubinsky.¹⁰⁶ This beverage is obtained by the fermentation of mare's milk and is consumed by the inhabitants of The Steppes. Three to 10 parts of the fresh milk are pitched with one part of kumiss and, during the next day or two, the liquor is stirred for about 15

minutes at intervals of two to three hours with specially made wooden sticks. In the course of 12 to 24 hours "new" kumiss is obtained; after a further period of 12 to 20 hours "medium" kumiss, which is the most general type of the beverage, is formed; "strong" kumiss is formed in 56 to 72 hours after pitching, as a result of the more advanced acidification and fermentation. "Medium" kumiss (which also serves for medicinal purposes) contains one to two per cent of alcohol and .6 to .8 per cent of lactic acid, while "strong" kumiss contains on the average 2.3 per cent of alcohol and 1.1 per cent of lactic acid. The contents of carbon dioxide and protein are .6 to 1.3 and 2.3 to 2.6 per cent, respectively. Four kinds of microorganisms were almost always found in kumiss, viz., the kumiss yeast, the kumiss bacterium, *Streptococcus lactis*, and *Bacillus acidi lactici*, Hueppe; of these the two latter are not specially characteristic of kumiss. The kumiss yeast is a bottom-fermentation yeast; it decomposes lactose and casein and produces the ester-like, aromatic substances of kumiss. The Kumiss bacterium is nonmotile, forms no spores, and has a temperature optimum of 30 to 35°C. (86 to 95°F.). There is a symbiotic relation between the two organisms. The kumiss fermentation is not a controlled one and probably depends much on accidental infection of the raw materials with the necessary organisms.

The results of studies on the bacteriology of kumiss are in fair agreement. Practically all indicate that it is a mixed fermentation carried on by yeasts and bacteria to which many different names have been given. Most of these, however, are members of the lactic acid group and the confusion is no more apparent here than in the other branches of dairy bacteriology. A few of the reports which have been made may be reviewed at some length.

Schipin¹⁰⁷ found three kinds of microorganisms in all examinations of kumiss, namely, *Saccharomyces*, *Escherichia acidi lactici*, and the kumiss bacillus. The last-mentioned organism decomposed lactose with a lactic and alcoholic fermentation. Quite similar conclusions were reached by Ginsberg.¹⁰⁸

According to Batschinskaja-Raitshenko,¹⁰⁹ kumiss as prepared in Ufa contains a lactic acid organism to which he gave the name *Bacterium orientale*. This organism was considered to be identical with the one isolated from kumiss by Berduikoff and Rubinsky. The organism seemed to be one of the active members of the lactic acid group of bacteria. The yeasts were of two types. None of them formed ascospores, and consequently the author called them *Torula kumiss I and II*. Both the bacterium and one of the yeasts are necessary for the production of kumiss. According to Belokopytowa and Smirnowa,¹¹⁰ properly prepared kumiss generally has three groups of microorganisms: *Lactobacillus bulgaricus*, *Torula*, and *Lactobacillus lactisacidi* (*Bacterium lactis acidi*, Leichmann).

Normal microflora of kumiss, according to Voitkevich,¹¹¹ is represented by lactic acid bacteria of the *Lactobacillus bulgaricus* type and yeasts of the genus *Torulopsis*. Preparation of the inoculum, described by Haldena,¹¹² is a somewhat tedious procedure. As is the case with other fermented milks, kumiss is quite bactericidal for pathogenic bacteria. This was ascribed by Kazberynk¹¹³ to its content of lactic acid. He worked with *Bacillus paratyphi abortus equi*.

Leben. This fermented milk used by the Egyptians resembles kefir. It is prepared from the milk of the buffalo, goat, and cow. The fermentation is started by pitching boiled milk with dried leben. After about six hours or somewhat longer in winter, according to Khoury and Rist,¹¹⁴ the beverage is ready. It contains a white, flocculent material in suspension and has a pleasant, fresh taste and a peculiar aroma. According to Khoury and Rist, five groups of microorganisms are involved in the leben fermentation, three bacteria and two yeasts. They claimed that better leben is secured when the yeasts are put into the milk first. Neither of the budding fungi (a yeast species and *Mycoderma* species) fermented lactose. These fungi are able to ferment only the products of lactose after it has been hydrolyzed by the bacteria.

Mazun. Mazun is a fermented milk made in Armenia from cow's, goat's, and buffalo's milk. Its bacteriology has been studied by Emmerling,¹¹⁵ Weigmann, Gruber, and Huss,¹¹⁶ Düggele,¹¹⁷ and others. A temperature of 30°C.(86°F.) was found to yield the best mazun. As with other fermented milks, a mixed flora of microorganisms has been found to be present. Düggele¹¹⁷ reported different microorganisms in it. Yeasts and lactic acid bacteria were common. Rod-shaped bacteria like *Streptococcus lactis* (*Bacterium g ntheri*) were present. The yeasts which were present fermented lactose with acid formation along with alcohols and some aromatic bodies. These microorganisms were said to be necessary for the preparation of good mazun. One of the yeasts seemed to have much to do with the development of an agreeable odor. Weigmann, Gruber, and Huss¹¹⁶ reported the presence of a lactose-fermenting, pastorianus-type yeast. They also reported the presence of *Bacillus mazun* and *Bacterium mazun*, both of which formed acid and coagulated milk.

Taette. This is a soured milk which has been prepared for centuries by peoples in the northern countries in Europe. It is a viscous, thick, coagulated milk with an agreeable acid taste. Olsen-Sopp¹¹⁸ made a microbiological study of this fermented milk and isolated the following organisms:

1. A streptobacillus corresponding to *Bacillus acidi lactis longus*, already described by Gerda Trosilli. This species was not easily cultivated. On gelatin it formed small, round colonies .6 to .8 mm. in diameter. The temperature limits were 3°C.(37.4°F.) and 35°C.(95°F.), the optimum being around 15°C.(59°F.).

117. D ggele. 1905. *Idem* 15, 577-600.

118. Olsen-Sopp. 1912. *Idem* 33, 1-54.

2. *Lactobacillus Taette*, very much like the yoghurt lactobacillus. This was a large rod, having an optimum temperature of 35°C.(95°F.).

3. Two yeasts. *Saccharomyces major Taette* and *Saccharomyces minor Taette*. These two species were separated by the fact that the former was much larger than the second, and also on the basis of ascospore formation. The latter never formed ascospores.

4. *Torulae*. These were not always present.

5. Mucedinaceae. *Monilia lactis Taette* and *Oidium lactis*. When these organisms were found they indicated an old product and an unsatisfactory one.

Olsen-Sopp stated that *Saccharomyces major* and *minor Taette*, *Lactobacillus Taette*, and *Bacillus acid lactis longus* were necessary for the production of Taette. Heinemann¹¹⁹ also investigated this fermented milk. He stated that this favorite food in Scandinavia was made by inoculating sweet cow's milk with the leaves of butterwort (*Pinguicula vulgaris*), which causes the milk to become thick and slightly stringy, with a slight cheesy taste and odor. A microscope examination of the samples showed streptococci in large numbers, mostly in diplococcus form. Two species of yeast were abundant, one being oval and the other a large organism with square ends, often forming long filaments. There were also some bacilli resembling *Escherichia coli* in shape and size, which proved to be Gram negative. There were a few large bacilli, resembling that group commonly found in milk, which forms larger amounts of acid than ordinary lactic acid bacteria. The streptococcus could not be distinguished microscopically from *Streptococcus lactis*, but its action on sterile milk differed in that it coagulated but slowly; after coagulation the coagulum was stringy, similar to the coagulum formed by *Lactobacillus bulgaricus* but in a smaller degree. The oval yeast gave the microscope picture of *Saccharomyces cerevisiae*. It ferments lactose and saccharose with violent gas production, levulose slowly, and maltose not at all. Cultures of this yeast in liquid beerwort impart a somewhat stringy consistency to the medium. The other yeast proved to be *Oidium lactis*, which is always present in milk and in this milk is probably responsible for a slight cheesy taste and odor.

Yogurt (Yoghurt). This fermented milk differs from other varieties by having a much higher content of acid and thicker curd. Yogurt requires more work in preparation than the other varieties. It is boiled and often reduced in volume about one-half. The fermentation is started by the use of a former batch of the product.

Kern¹²⁰ was led to investigate the morphology of the fermenting agent of yogurt and called it *Dispora caucasicum*, a name of inaccurate taxonomy. Other bacteriological studies were reported by Beijerinck,¹²¹ Freudenreich,¹²² Khoury and Rist,¹¹⁴ and Cohendy and Grigoroff. Kuntze¹²³ called attention to the great variability of the bacteria found in yogurt and matzoon by different observers. From his own researches he thought

that some, if not all, of these species described as new were only varieties of species previously known. Hastings and Hammer¹²⁴ examined many samples of milk from different sources which were incubated at 37°C. (98.6°F.) and in all cases developed a greater acidity than could be accounted for by the presence of *Lactobacillus lactis acidii*, indicating that the causal organism, a bacillus closely related to *Lactobacillus bulgaricus* and *Bacillus casei* E, has a wide distribution. According to Guerbet, yogurt is identical with leben which has been studied by Rist and Khoury. They claimed that a streptobacillus decomposed the lactose into glucose and galactose. These sugars were fermented by yeasts to alcohol. Guerbet stated that the alcohol came from this bacillus. Duchacek¹²⁵ made tests of several strains of *Lactobacillus bulgaricus*, one strain coming from a commercial medicinal source and another which was recognized as the true *Lactobacillus bulgaricus*.

The latter strain was found to be much more sensitive but was readily killed by acids and would develop only in certain culture media which contained sugars. The other strain was much less sensitive and, in contrast to the true *Lactobacillus bulgaricus*, readily digested proteins. Attention was directed to the difficulty of completely sterilizing milk, to the ease with which the true *Lactobacillus bulgaricus* is destroyed and the great possibilities of such destruction taking place in commercial preparations, and to the predominance in these of other strains of bacteria which remain owing to incomplete sterilization. Boersma¹²⁶ reported that the growths known as yogurt plants are true kefir grains consisting of *Lactobacillus caucasicus* B. Yeast did not contribute to the structure of these grains even though they were present. Live yogurt bacteria were reported in dry tablets eight years old, by Klebs,¹²⁷ and in milk cultures five and six years old. Their strength seemed to have been diminished and it required several transfers to bring them back to an active condition. In the old cultures, numerous coccus-shaped forms existed as well as in the first subcultures. After several transfers these dropped out and the usual rods appeared. Weil¹²⁸ believed that the preparation of yogurt should recognize the typical flora, absence of contaminations and pathogenic bacteria, and the proper methods of preparation. The flora was said to consist of *Lactobacillus bulgaricus* which produced the acid and desirable aroma and a coccus. *Lactobacillus bulgaricus* and *Streptococcus lacticus thermophilus* were used by Rosell.¹²⁹ He experienced little trouble in making yogurt.

Kuban. Bogdanoff¹³⁰ observed that kuban fermented milk was characterized by lactic acid and alcoholic fermentations. The flora consisted of a lactic acid-producing streptococcus much like *Streptococcus hollandicus*, a lactic acid-producing, rod-shaped bacterium like *Lactobacillus bulgaricus*,

and three types of yeast. All of these bacteria worked together. Care must be used in heating the milk.

Survival of Pathogenic Bacteria in Fermented Milks. Should these products be made from raw materials which are not clean and sanitary or should they be improperly handled, it is desirable to know whether common pathogenic bacteria could survive in them. Results of investigations which bear on this problem have been discussed in Chapter 9. It has been found, in general, that high acid content is detrimental to such bacteria as *Eberthella typhosa* and members of the genus *Salmonella*. Kazaryan¹³¹ observed that .1 per cent of lactic acid hindered the development of the bacteria just mentioned; greatest resistance to this acid was exhibited by *Salmonella schottmülleri* and coliform bacteria. While these bacteria were inhibited they were not destroyed, which makes it possible for the fermented milk studied by Kazaryan to disseminate disease. Sircana,¹³² working with yogurt, found *Eberthella typhosa* to neither grow nor survive. He believed, therefore, that fermented milk was not a dangerous vehicle for pathogenic bacteria. Nicholls, Nimalasuriya, and de Silva¹³³ considered fermented milk to be safe even where sanitation was primitive. *Eberthella typhosa* and *Shigella dysenteriae* inoculated into whey of fermenting milk did not survive beyond three hours.

Less information seems to be available about longevity of *Mycobacterium tuberculosis* in sour milk. Kliewe and Schuppener¹³⁴ observed *Mycobacterium tuberculosis* (hominis) to survive for seven days and the bovine variety for 20 days. Milk from which fermented milks are made may come from tuberculous cattle. Broers and Ten Sand¹³⁵ reported that guinea pigs several days old, which had been inoculated with kefir, developed tuberculosis. Cells of *Eberthella typhosa* did not resist the kefir fermentation very long, being destroyed after 48 hours. Similar conclusions have been reached by others who studied the question for cream ripening.

CHAPTER 13

INTESTINAL MICROBIOLOGY

Food microbiologists have a legitimate interest in intestinal microbiology. Severe intestinal infections and intoxications may be caused by microorganisms in foods; they may also function in digestion by aiding decomposition of various complex substances. Kelemann¹ stated that bacterial enzymes decomposed much of the sucrose in the alimentary tract of animals and made it available as simpler sugars. It has been known for some time that various bacteria in the intestines may also synthesize vitamins. One of the recent reports on this latter subject is by Burkholder and McVeigh² who showed the formation of B-vitamins by various bacteria.

Intestinal Flora in Childhood. At birth the alimentary tract is sterile but becomes infected in a few hours. Bacteria enter through both the mouth and the anus. Some of these bacteria may be harmful, while others are either beneficial or harmless. Dreyfus³ found that the intestinal tract of the newly-born infant on different milk diets was sterile up to the 15th or 20th hour. At about 20 hours, infection sets in and increases up to about the third day. After the fourth day, the flora becomes fixed. When the child is put on a mixed diet, there is a change, the extent of which depends on the amount of milk which is left. Heineman⁴ suggested that, at this time, the gastric secretion is small and the stomach offers no serious obstacle to the passage of bacteria through it into the intestines. This first infection is undoubtedly a heterogeneous one which becomes more homogeneous as those types which find the conditions in the intestines unsuitable, drop out. The high carbohydrate diet of the infant, rich especially in lactose, causes *Lactobacillus bifidus* to establish itself. As the diet is extended *Escherichia coli* enters, since it can live either in the presence or absence of lactose. Hauschild⁵ also reported gram-positive cocci, yeasts, sarcinae, and aerobic sporeformers in the intestines of normal infants. *Escherichia coli* was absent. In cases of toxicoses, the cocci were replaced by gram-negative cocci. *Escherichia coli* was found in cases of diarrhea. Bosworth, Wilder, Blanchard, Brown, and McCann,⁶ in seeking an explanation for the formation of large amounts of acetic acid in the stools of infants receiving a commercial dry milk, isolated strains of *Aerobacter aerogenes* which decomposed citric acid, forming water, carbon dioxide and acetic acid. *Lactobacillus bifidus* formed a mixture of acetic and oxalic acids. Other bacteria which fermented citrates were isolated

but not identified. The close relationship between bacteria in the intestines and those in the food was also shown by Ford, Blackfan, and Batchelor.⁷ They found that the bacteria with which the food of children is infected are about the same as those found in the feces. They found *Bacillus cereus* and *Bacillus albolactis* most commonly present, while *Bacillus mesentericus* and *Bacillus pseudotetanus* were also found. Ford and his colleagues found that pasteurized milk, protein milk, buttermilk and farina used in children's diet were seeded with sporebearing bacteria, the spores of which were capable of withstanding the heat used in their preparation. It was believed that the presence of sporebearing, gram-positive bacteria in the intestines was due to such bacteria in the food. They believed that both the food and the stools should be studied when reaching conclusions in intestinal bacteriology.

The multiplication of gram-positive bacteria in the intestinal tract of infants was favored by the addition of fats and certain sugars; lactose was especially active. The amount and nature of the fatty acids and soaps in the intestines determine the relative abundance of gram-positive and gram-negative bacteria. Thus it is seen that there are two distinct periods in the life of a child as far as the intestinal flora is concerned, the first when it is receiving almost entirely a milk diet and the second when that is supplanted by a more extended diet which not only introduces a varied flora but encourages such a flora by a wider variety of food materials.

Effect of Diet on Intestinal Flora. Students of the subject of intestinal bacteriology have accepted the dictum that the character of the bacterial flora is determined by the diet. It is believed that the ingestion of foreign bacteria, even in large numbers does not displace the common intestinal types. In order to cause a microorganism to take up its abode in the intestines for an appreciable time, a suitable diet must be ingested and an organism used which is preferably an intestinal species. This is further indicated by the fact that from the great variety of bacteria which gain entrance to the alimentary tract, only a few species are able to establish themselves.

Much work has been done by various investigators from which facts have been well established with regard to changes induced in the intestines by variations in the diet. The changes in the flora resulting from various diets have been measured in terms of certain large groups and rarely in terms of any one of few organisms. These groups which have thus been used may be enumerated as follows:

- I. Putrefactive group
Escherichia coli, *Clostridium welchii*.
- II. Aciduric group
Lactobacillus bulgaricus, *Lactobacillus acidophilus*, *Lactobacillus bifidus*
- III. Amylolytic group
Glycobacter amylolyticus, and others.

7. Ford, Blackfan, and Batchelor. 1917. J. Amer. Med. Assoc., 68, 1776.

Herter and Kendall,⁸ working with monkeys, studied the effect on the intestinal flora of sudden changes in the diet. After the flora from a distinctly protein diet had been established, the diet was changed to one of milk and sugar. After this change they were able to detect a change in the intestinal flora and mental condition of the animal. Also in the urine, putrefactive products were quite evident. In the intestines, the acidophilus group of organisms was changed to a proteolytic group. This was one of the first papers from which definite conclusions could be drawn. The authors suggested that in a disease where either the acidophile or putrefactive group tended to become established, a rapid alteration in the diet would tend to prevent either group of bacteria from becoming established. Herter,⁹ in a later paper, reported the same conclusions.

The relation of diet to intestinal flora was also studied by Cannon¹⁰ with white rats. When kept on a stock diet of oats and carrots, at the end of two weeks the colon-acidophilus ratio was 1 to 99; on a protein diet consisting almost exclusively of raw meat there was a colon-acidophilus ratio of 99 to 1. When variations intermediate between these two diets were used, varying colon-acidophilus ratios were secured. Grain foods, lactose, and dextrin led to a predominant aciduric flora, while animal proteins led to a predominance of organisms of the gas-producing proteolytic types, both aerobic and anaerobic. Vegetable proteins accelerated the appearance of a distinct antiputrefactive effect, favoring development of *Lactobacillus acidophilus*. These results were also obtained with two human adults. Hudson and Parr¹¹ also reported quite similar results. Torrey,¹² as did Cannon, also found that mammalian tissue was the only one which encouraged to any extent the growth and activity of the obligate putrefactive bacteria within the intestines. Four years before, Torrey¹³ observed the results of a high calorie diet on the fecal flora of typhoid patients. When large amounts of lactose were fed, there was a change to a flora in which *Lactobacillus acidophilus* predominated. That the factors which control the intestinal flora are varied is suggested by the work of Torrey and Rahe,¹⁴ who found that certain undesirable strains of *Escherichia coli* could be removed from the intestinal tracts of dogs by means of large doses of autogenous bacteria.

One hundred and seventy-three rats were fed 12 different diets by Porter and Rettger.¹⁵ On the stock diet the "normal" bacterial flora of the young white rat was simple, especially in the upper segments of the alimentary tract, the flora being made up largely of *Lactobacillus acidophilus* type of aciduric microorganisms. Bacteria became increasingly more abundant in the lower sections of the small intestines and cecum

where an appreciable number of coliform bacteria were found. Yeast-like fungi were observed in all segments in small numbers. This "normal" flora was said to be altered throughout the intestinal tract by food or starvation, but was fairly stable irrespective of the diet. Various salts were observed by Eppright, Valley, and Smith¹⁶ to alter the intestinal flora. On low salt intakes the usual aciduric intestinal flora with *Lactobacillus acidophilus* was replaced by a flora consisting of coliform and proteus types and *Streptococcus fecalis*. The Osborn and Mendel salt mixture maintained a flora rich in *Lactobacillus acidophilus* and restored the resistant aciduric bacilli previously altered by ingestion of a diet deficient in inorganic salts.

Effect of Fasting and a Low-Protein Diet on Intestinal Flora. Blatherwick and Hawk¹⁷ studied the effect of fasting and a low- and high-protein intake on the bacteria in the intestines by determining the amount of bacterial nitrogen in the feces, according to the method mentioned elsewhere in this chapter and the output of urinary indican. They found no relation between output of bacteria in the feces and the amount of indican in the urine. By means of a seven-day fast, the bacterial nitrogen excreted by a 76-kg. man was reduced from 1.571 to .101 gm. The actual weight of excreted bacterial substance was reduced from 14.336 to .920 gm. per day. The output of bacterial nitrogen and bacterial substance was about the same during a fast and on a low-protein intake. Ingestion of a high-protein diet caused an increase in the above amounts. Unfortunately a qualitative study of the bacteria in the feces was not made, and to secure such information it is necessary to consult the work of others. Herter and his colleagues, the work of whom has been summarized by Herter,¹⁸ have given definite proof that a protein diet favors the proteolytic group. Rettger and his colleagues, on the other hand, have studied the effect of milk and carbohydrate feeding. The experiments were made with laboratory animals and man. Hull and Rettger¹⁹ found that lactose, when taken by adults along with their usual food, caused a shift in the flora to the acidophilic group of bacteria. *Lactobacillus acidophilus* and *Lactobacillus bifidus* appeared, with the former more abundant. The most practical diet, however, to produce these results, was a combination of milk and lactose. *Lactobacillus bulgaricus* was not found, which is in accord with the work of others. For a more complete discussion of this subject, see Chapter 12.

Fasting has a decided effect on intestinal bacteria. As quoted above, Blatherwick and Hawk,¹⁷ during fasting, noticed a decided reduction in the amount of bacterial nitrogen and bacterial substance. Sisson²⁰ found that, after periods of starvation, there is a definite decrease in the number of bacteria in contrast to the usually large number. No change in the kind

of organism after starvation was noted. The greatest decrease in the number of bacteria was noticed in the duodenum. Sisson regarded the condition produced by starvation as one of relative amicrobism. When Poppens²¹ studied the effects of fasting on the bacterial flora of the stomach and duodenum, using dogs fed bread and meat until 14 hours before the operation, the bacteria found varied in type. Cannon and McNease²² reported that a meat diet caused a neutral reaction in the contents of the cecum and colon; they were foul-smelling and contained indol. The flora was of a gas-producing variety and proteolytic with *Lactobacillus acidophilus* at a minimum. The addition of lactose caused a distinct change in the reaction of the contents of the cecum and colon. Cushing and Livingston reported relative amicrobism following a fasting period of 24 hours. Sisson²⁰ also observed a reduction in the bacterial content, the greatest reduction occurring in the duodenum. Fasting never brought about a condition of complete sterility. The above results were, in general, confirmed by Schnorbusch.²³

Effect of Copious Water Drinking on Intestinal Flora. The influence of copious water drinking on the intestinal flora has not been studied as much as other factors. Fowler and Hawk²⁴ noticed a decrease in the total nitrogen appearing as bacterial nitrogen. The following weights of fecal bacteria were excreted per day during the periods mentioned:

Preliminary	5.327 gm. per day
Water period	4.579 gm. per day
Final period	3.280 gm. per day

Hattrem and Hawk,²⁵ by means of copious water drinking, obtained a decrease in putrefaction and stated that it was probably due to a decrease in the activities of indol-producing bacteria following accelerated absorption of products of protein digestion. Copious water drinking (1000 ml.) caused a decrease of indican in the urine which was accompanied by an increase of ethereal sulfates. The drinking of distilled and softened waters were found by Sherwin and Hawk²⁶ to cause a decrease in intestinal putrefaction as measured by urinary indican. It is possible that the character of water used for drinking influences the type of microorganisms, but few data are available upon which to base conclusions.

Effect of a High-Protein Diet on Intestinal Flora. A high-protein diet has been found to induce the predominance of bacteria which can utilize proteins. After Metschnikoff propounded his interesting theory on the relation of the intestinal flora to longevity and well-being, many investigations were instituted to prove the truth of his statements. Among the early investigators to study the question was Herter.¹⁸ Torrey¹² fed dogs a protein diet over a long period of time and, furthermore, studied the transforming ability of animal as compared with vegetable proteins. A

considerable number of dogs were kept for a varying length of time on boiled beef heart. A putrefactive flora of a pronounced and uniform type appeared. Under these conditions, the flora was dominated by the gram-positive, sporebearing, anaerobic bacilli to the same extent that *Lactobacillus bulgaricum* dominates when a diet of lactose or dextrin was fed. The *Clostridium welchii*-like organisms were found throughout the intestines and were in almost pure culture in the small gut. On this meat diet *Escherichia coli* (*Bacterium coli*) was markedly suppressed, and *Lactobacillus acidophilus* and *Bacteroides bifidus* (*Bacillus bifidus*) practically eliminated. Bacteria producing hydrogen sulfide from peptone were markedly numerous, especially members of the proteolytic group. Different results were secured with a fish diet. A high fish diet did not encourage the growth of sporebearing bacteria, of either aerobic or anaerobic type. Instead of *Clostridium welchii*-like flora as occurred when beef heart was fed, Torrey observed an *Escherichia coli* flora. *Clostridium welchii*, *Lactobacillus acidophilus*, and streptococci were present in small numbers or entirely absent. A fish diet also seemed to favor a flora of organisms which formed hydrogen sulfide from proteins more than any other diet. Torrey,²⁷ in a later report, published the results of experiments on the same subject carried out with human beings. Two of the subjects were kept on an exclusive meat diet for over a year. Change from a mixed to a whole-meat diet caused an abrupt drop in the total bacteria amounting to about 50 per cent. In one subject it reached 76 per cent during the 13th month. This decrease was attributed to the suppression of lactic acid-producing types, Enterococci and Streptococci and to a lesser extent, *Escherichia coli*. Free spores and sporeforming bacteria remained at about the same level. Spirochaetes disappeared. The interesting observation was made that the high-meat diet did not induce greater proteolytic activity than a mixed diet. Furthermore, no evidence was gathered that a long-continued exclusive meat diet favored the development of putrefactive conditions in the colon. Such conclusions are somewhat different from the general opinions which are prevalent on this question. Although milk casein is animal protein, it did not seem to create putrefactive conditions to the same degree as did meat. Vegetable proteins were said to stand in strong contrast to animal proteins, especially meat, in that they did not offer the slightest encouragement to the growth of intestinal putrefactive types of bacteria. This is an interesting observation which was confirmed by Cannon.¹⁰ Cannon stated that his experiments agreed with those of Torrey in that vegetable proteins not only reduced the relative proportion of proteolytic types, both aerobic and anaerobic, but also encouraged the overgrowth of a non-gas-producing aciduric flora. Animal proteins, on the other hand, such as meat, fish, and eggs, led to an enormous overgrowth of gas-forming proteolytic types. Hull and Rettger²⁸ had reported in 1917 that a high-protein diet of meat or other proteins increased the indol-producing bacteria and other organisms of the putrefactive type. The

contradictory conclusions which have been reached by those who have studied this subject are not easy to explain. It is very probable that other factors than the one under study may have had some effect.

Influence of Hydrogen-Ion Concentration on Intestinal Flora. The actual acidity of the intestinal contents of the cecum and colon, according to Cannon and McNease,²² is one of the important factors influencing the bacterial flora. With a high-protein diet the reaction of the contents of the cecum and colon was pH 7.0 to 7.1; the addition of lactose may lead to a pH in the cecum of 4.6 with 6.2 in the lower colon. The simplification of the intestinal flora varied directly with the hydrogen-ion concentration. A pH of 7.0 is characteristic of a gas-forming proteolytic type; an increasing acidity causes a diminution in proteolytic forms and their replacement by aciduric types. Hull and Rettger,²⁸ however, did not observe a relation between the character of the intestinal flora and the reaction of the intestine. They found, as a rule, the highest acidity in the duodenum and the lowest at the ileocecal valve. Robinson²⁹ determined the hydrogen-ion concentration of the feces from several human subjects by means of the electrometric method. The reaction was found to vary ordinarily between pH 6.5 and 7.5 although occasional isolated values were observed which were outside of this range. However, the normal fecal reaction of healthy men was between pH 7.0 and 7.5. Robinson made the interesting observation that drinking one quart of *Lactobacillus acidophilus* milk and *Lactobacillus bulgaricus* milk daily did not change the reaction of mixed feces. Cheplin and Rettger³⁰ made the same observation. Hudson and Parr,¹¹ however, found that a change in the intestinal flora from a heterogeneous, gram-negative type to a simplified gram-positive type was also accompanied by a change in the reaction from nearly neutral to distinctly acid.

Investigations seem to indicate that the reaction of the intestines does not vary within wide limits. It is perhaps difficult to decide whether the reaction determines the type of the bacterial flora or whether the flora is responsible for the reaction. Long and Fenger³¹ studied the reaction of intestinal contents of both men and animals. Arnold³² found cocci and *Escherichia coli* seldom present in the upper part of the small intestine as long as there was a predominance of acid-reacting substances. The subject was discussed again by Arnold and Brodny.³³ A change in the bacterial flora of the duodenum and upper jejunum was noticed when the normal reaction of the contents was changed from slightly acid (pH 5 to 6) to a neutral or alkaline reaction (pH 7 to 8). The reaction of this region was also said to depend to a great extent on normal gastric secretory function.

No correlation was observed by Weinstein, Weiss, and Gillespie³⁴ between pH in the small intestine and its *Lactobacillus acidophilus* content

in white rats on three different diets; in the colon there was some degree of correlation. The nature of the diet and the portion of the intestines examined are important in determination of the average pH and content of *Lactobacillus acidophilus*. Hydrogen-ion concentration and the volatile acid content of the intestines, according to Bergeim,³⁵ must not be overlooked in investigations on intestinal flora. He studied the effect of formic, acetic, butyric, and lactic acids on growth of yeast and *Escherichia coli* over the range of pH and acid concentration likely to occur in the intestines. Above pH 6.5, these acids had little effect. Below pH 4, the pH itself became important. In the pH range of 5 to 6 where pH itself was not inhibitory, the fatty acids, even in low concentrations, had a marked effect on growth. In this range acetic and butyric acid were the most effective and lactic acid had little influence. *Lactobacillus acidophilus* was very resistant. Bergeim believed that volatile acids could not be disregarded when studying the effect of acidity on the intestinal flora.

Effect of Intestinal Absorption on Intestinal Flora. Dragstedt³⁶ and his colleagues reported that in cases of complete obstruction or stasis in the passage of the intestinal contents, a proteolytic flora is induced irrespective of the diet of the individual. It was stated that carbohydrates, such as dextrin and lactose, were probably absorbed in the upper part of the intestines and therefore exerted no influence on the character of the flora in the lower parts of the intestinal tract.

Relation of Vitamin-Deficient Diets to Bacterial Flora. Creekmur³⁷ studied the intestinal flora of rats on a normal diet and one deficient in Vitamin A. In most of the animals, on the deficient diet streptococci disappeared completely. There seemed to be no change in the proportions of bacteria fermenting glucose, lactose, and sucrose or in the proportion of H₂S forming bacteria. The feces of the animals on the deficient diet became dry and hard with a distinct decrease in the total number of bacteria. The addition of vitamin A in the form of a few drops of cod liver oil daily produced a normal condition. Animals on vitamin-deficient diets are probably abnormal; the bacterial flora would be markedly influenced by many factors.

Relations of a Milk Diet to Intestinal Flora. The effect of milk on intestinal flora has been rather extensively discussed in Chapter 12, where the use of fermented milks in the diet was taken up. Hull and Rettger,²⁸ as a part of the extensive investigations of Rettger on the effect of diet on intestinal bacteria, studied the influence of milk. They stated that the beneficial action of milk in changing the flora to one in which acidophilic bacteria predominated was due mainly to its lactose content. Bergeim's³⁸ work on ferric oxide as an index of intestinal putrefaction seemed to indicate that milk tended to depress the formation of reducing substances by bacteria in the intestines. This subject is discussed further in Chapter 12, where the influence of fermented milks on intestinal bacteria is reviewed.

Effect of Carbohydrates on Intestinal Flora. Sugars, when added to the diet, uniformly have favored the growth of acidophiles. Torrey¹² found that when lactose and dextrin were added to the diet of dogs, acidophiles increased in numbers. Rettger and his collaborators have shown the same thing. Hull and Rettger,²⁸ using white rats, studied the effect of carbohydrates on the character of the intestinal flora. This was a continuation of Rettger's³⁹ work on the same subject. *Lactobacillus acidophilus* (Moro) and *Bacteroides bifidus* (Tissier) were said to be common inhabitants of the intestinal tract of white rats and man, although their numbers may vary greatly. They claimed that diet was the most important factor determining bacterial flora. Lactose fed in two- to three-gram quantities brought about a complete transformation in the flora in two to three days. Milk required a longer time and did not cause as complete a transformation. It is well known that *Lactobacillus acidophilus* is commonly present in the intestinal tract and in various other places in the body. Naujoks⁴⁰ isolated it from the vaginal secretions as well as in two-thirds of his pregnancy cases. It was said to be identical with *Bacillus vaginalis minor*. The organism appears in the rectum of breast-fed infants in from four to seven days, and in the mouth after seven days. Lauter,⁴¹ studying *Bacteroides bifidus*, believed that intestinal infection was by mouth. The value and importance of milk rests on its content of lactose, which is absorbed slowly from the intestines. Foods which are made up of starch stimulate the establishment of an aciduric flora. Bread, however, which contains cooked starch, had little effect. Lactose in amounts from 250 to 300 grams per day brought about a marked change in the flora of the human intestinal tract. These results were confirmed by Cruickshank⁴² in feeding experiments on rats. A diet with high-carbohydrate content produced a simplified flora in the intestines of rats but failed to effect a radical transformation to an aciduric flora. Lactose and dextrin, when added to a diet of bread, meat, and oats, quickly changed the intestinal flora to aciduric types. Saccharose had a much less marked effect. Maltose, glucose, galactose, and levulose produced no change. Acidophilus milk caused a change to an aciduric flora and the change was more marked when lactose was added. Cruickshank believed that the value of acidophilus milk in the diet was not due to its bulk or acidity but to the combination of the living microorganism with the unfermented lactose in the milk.

Implantation of *Lactobacillus bulgaricus*, even by feeding large quantities, was not successful. Torrey¹² confirmed these discoveries with dogs. Not all carbohydrates had the same value in stimulating the appearance of an aciduric flora. He placed the sugars in the following order: dextrin, lactose, saccharose, maltose, and dextrose. With unboiled milk *Escherichia coli* and streptococci predominated, while with boiled milk streptococci and *Lactobacillus acidophilus* were favored. Bass⁴³ reported the

43. Bass. 1923. South. Med. J., 26, 1-7.

same results with lactose feeding. Daily ingestion of sufficiently large amounts of lactose caused a change to a *Lactobacillus acidophilus* flora. In some cases, more than 300 grams of lactose per day were required to cause a shift in the flora. Since such amounts of lactose are too large to be continued over a long period, this method has certain limitations. The results of feeding acidophilus milk were in accord with the statements of Rettger and others. Cheplin and Rettger⁴⁴ emphasized again the intimate relation between the chemical constitution of the diet and the nature of the bacteriological flora. The addition of two (2) grams of lactose or dextrin to albino rats, being fed a diet of beef and bread, stimulated the proliferation of *Lactobacillus acidophilus*. The organism completely dominated the intestinal flora in six days. *Lactobacillus bulgaricus* could not be implanted so easily or so completely and these workers suggested that Metschnikoff and his colleagues, when reporting the results of sour milk therapy, really observed *Lactobacillus acidophilus* and not *Lactobacillus bulgaricus*. Even when large numbers of *Lactobacillus bulgaricus* were added to the diet, the organism could not be established in the intestine.

As might be expected from the above discussion, Hull and Rettger²⁸ noticed that the presence of "corn-starch" in the diet appeared to foster the amyolytic bacteria; the ingestion of grain was said to favor the development of fusiform bacteria. Perhaps the real reason why a large amount of lactose or dextrin in the diet leads to such a predominance of *Lactobacillus acidophilus* is not known. Some have suggested that it was due to the fact that lactose persists so much farther along the alimentary tract. It is not entirely absorbed or fermented before the large intestine is reached. One may wonder why an undesirable fermenter of lactose does not flourish instead of *Lactobacillus acidophilus*. Kendall⁴⁵ suggested that feeding liberal amounts of lactose to infants might lead to an excessive development of *Clostridium welchii*, an inhabitant of the alimentary tract. In opposition to this is the experience of Cheplin and Rettger and others who have always reported a decrease if not entire elimination of *Clostridium welchii* and *Escherichia coli* as well. Kopeloff and Cohen⁴⁶ put the investigation of the problem on a practical basis by using 45 human subjects. Without enumerating details of technic, the conclusions which they reached may be given. The ingestion of 10 grams of lactose did not transform the intestinal flora; 50 grams daily, however, transformed the flora in four out of 15 subjects. Ingestion of 100 grams of lactose daily transformed the flora in three out of 15 subjects. The presence of *Lactobacillus acidophilus* before lactose feeding did not seem to aid in transforming the flora. These experiments were carried out over a period of three to eight months.

Addition of lactose and *Lactobacillus acidophilus* to a well-balanced diet caused an increase in cocci at the expense of gram-positive and gram-negative bacilli in the ileum, according to Paulson.⁴⁷ This indicated that there may be some alteration in the flora of the ileum and that *Lacto-*

bacillus acidophilus is washed down or may multiply to some extent in the human ileum. According to Sanborn,⁴⁸ the alteration of the intestinal flora by a high-carbohydrate diet is largely dependent on the flora already established.

Dried fruits may be presumed to be rich in carbohydrates and therefore function in influencing the bacterial flora as do carbohydrates. Such was the finding of Weinstein and Weiss⁴⁹ when they fed banana powder, apple powder, and raisins to white rats on a high-protein diet. *Lactobacillus acidophilus* predominated in the intestines. Prunes had little effect. They attributed the effect of dried fruits to their sugar and mineral salts content.

Effect of a High-Fat Diet on Intestinal Flora. Since fewer bacteria are able to split fat than proteins, one would not expect a high-fat diet to cause much change. Such was the case when Torrey¹² fed butter to dogs. No new types of bacteria were introduced, but some species normally present were somewhat suppressed. The streptococci seemed to be especially influenced. The numbers of *Escherichia coli* (*Bacterium coli*) were frequently reduced, but aciduric bacteria of the *Lactobacillus acidophilus* type were least affected.

BACTERIA IN THE MOUTH

All kinds of bacteria enter the mouth in food and drink. Consequently, if all of these transient types are considered in studies on the mouth flora, the flora would be quite heterogeneous. However, study of the question narrows the flora to certain species which are always present.

Bloomfield⁵⁰ found that bacteria and fine dust particles disappeared in a very short time. He found that they neither remained nor spread over the mouth. Carbon particles seemed to be removed in from 15 to 30 minutes. He found that the tonsils were normally so protected by the pillars that the particles from the mouth were swept by without infecting them. The upper part of the pharyngeal wall was also untouched. This would seem to indicate that many of the bacteria in food hurry through the mouth and do not contribute to its flora.

Appleton, Klein, and Palmer,⁵¹ after developing a method for measuring the rate of elimination of bacteria from the mouth, used it to follow elimination of a test organism, *Serratia marcescens*. They observed that this organism eventually disappeared when introduced into the human mouth. The rapidity depends on various factors.

Filamentous bacteria have also been found in the mouth by Bibby and Berry⁵² who divided some 83 strains into seven groups. Six of them had distinct characteristics. Most of them had characteristics of the genus *Leptotrichia*. Most of them were classed as *Leptotrichia buccalis*.

Germicidal Action of Saliva. Data available on this subject are neither conclusive nor extensive. Huggenschmidt,⁵³ from a study of the various

factors which contribute to the protection of the sputum, mechanical action of the saliva, action of the mucous membrane and bacterial antagonism, concluded that the mechanical action of the sputum was the most important factor. Sanarelli⁵⁴ filtered saliva through a Chamberland filter and tested the bactericidal action of the filtrate. He believed that saliva did possess a germicidal action quite similar to that exhibited by other body fluids, such as blood, aqueous humor, etc. The speed of the reaction depended upon the initial number of bacteria introduced into the saliva. If a small number of cells (three or four hundred) were introduced, all were killed in a short time, but when a few thousand cells were introduced, there was usually a decrease followed by an indefinite increase. With *Corynebacterium diphtheriae* and the Pneumococcus no germicidal action was noticed. They were found alive after 28 and 40 days. The cause of the germicidal action was not determined. Gordon⁵⁵ carried out his experiments on this subject in culture media, and found a germicidal action against the Meningococcus, which he attributed to the antagonistic effect of other bacteria in the saliva. These were supposed to be mixed streptococci. Van der Reis⁵⁶ could observe no bactericidal activity in saliva against a number of bacteria in test-tube experiments. *Escherichia coli* (*Bacterium coli*) sprayed into the mouth remained for many days. This last statement is not in accordance with the conclusions of Bloomfield. In fact, van der Reis claimed that this organism had colonized on the tonsils.

The subject was studied by Barnes⁵⁷ with fresh saliva sterilized by filtration. Loopfuls of broth cultures of the organisms were inoculated into about .4 ml. of saliva. No germicidal effect could be observed with the pneumococcus, streptococcus, staphylococcus, or influenza bacillus. Indeed the staphylococcus and pneumococcus were favored.

The saliva of various animals, dogs, cats, rabbits, monkeys, and goats, was studied by Clairmont. The saliva seemed to exert a mechanical action more than a real germicidal effect. Whether saliva is shown to exert bactericidal action is determined by the conditions under which the experiments are carried out. If the investigator uses a very delicate organism, one which is quite susceptible to unfavorable conditions, he might conclude that lack of growth is due to destruction of cells by the saliva. On the other hand, it might be due to unfavorable conditions of culture.

Weigmann and Noeske⁵⁸ observed inhibition by human saliva of growth of *Corynebacterium diphtheria*, *Bacillus subtilis*, and *Bacillus anthracis*. The activity of the saliva of different individuals varies greatly. Short exposure to boiling and 30 minutes' heating at 56°C. (132.8°F.) destroys it. The property was also said to be destroyed by filtration and centrifugation. The property soon disappears from saliva. Piasecka and Zeyland⁵⁹ observed an inhibitory action of saliva on *Mycobacterium tuberculosis*. In

contradiction to the results of Weigmann and Noeske, they did not observe that heating at 56°C. destroyed it. They attributed this action to unknown factors. The antibacterial activity of saliva was attributed by Van Kesteren, Bibby, and Berry⁶⁰ to at least two antibacterial factors, one of which was said to resemble lysozyme. Each of these agents acted more specifically on certain microorganisms.

THE STOMACH

The bacteriological aspects of the stomach have been concerned mostly with its diseases. The bacteria of the stomach gain entrance with the food and drink. The germicidal action of the saliva may probably be neglected as a factor influencing the number of bacteria passing through the mouth. The types of bacteria found in the stomach are undoubtedly determined by the kind of food taken in and the types of microorganisms in this food. Henneberg⁶¹ analyzed 17 fresh stomachs and found the following organisms: *Oidium lactis*, *Torula*, *Saccharomyces Minor*, *Lactobacillus beijerinckii* (*B. beiejrinskii*), *Sarcinae*, lactic acid bacteria, and certain other forms. Aronovitch, Coleman, and Einhorn have published similar data for the stomach. Kopeloff⁶² reported that many of the bacteria in the stomach resulted from swallowing saliva. Dukes⁶³ tried to find out whether bacteria were digested in the stomach. He reported that bacteria did not absorb proteolytic enzymes for they seemed to be protected by means of a lipoidal envelope.

Germicidal Action of Gastric Juice. The gastric juice is the normal secretion of the stomach. It contains between two to three per cent solids and about .2 per cent of free hydrochloric acid, which is the most powerful of any acid combination in the stomach. A condition of hyperacidity exists when a decidedly greater amount of hydrochloric acid is present than normally, and hypoacidity when the amount of acid is below normal. During conditions of hypoacidity fermentation may be active with the formation of lactic and butyric acids. Some hold that gastric ulcer and gastric catarrh may be due to reduced acidity.

That the gastric juice is germicidal was noticed by Spallanzani in 1734. When he moistened meat with gastric juice, it did not putrefy. Meat which was not so treated but which was moistened with other substances, such as water, developed a putrid odor very quickly. He opened a snake 18 days after it had swallowed a lizard and while the lizard was partly digested, it had not decomposed. Other experiments by this early scientist demonstrated that putrefaction could be stopped by gastric juice.

Somewhat the same technic was used by van der Reis.⁵⁶ After feeding *Serratia marcesens* (*Bacillus prodigiosus*) he was able to isolate it from the stools, which would indicate that it had not been killed in the stomach by the gastric juice. He also dipped pieces of bacon and apple seeds in cultures of *Serratia marcesens* (*B. prodigiosus*) and staphylococcus, tied

threads to them and had them swallowed. Bacteria could be cultivated from them when they were withdrawn two hours later. The experiments were repeated before, during, and after meals. The hydrochloric acid was said to have received undue credit for destroying bacteria in the stomach. William Beaumont, when studying the gastric secretion of Alexis St. Martin, also suggested that gastric juice checked putrefaction.

Koch⁶⁴ fed cholera vibrios to dogs and after a few hours found that they had been destroyed. He stated that cholera vibrios were destroyed in the stomach under normal conditions, and that if they passed through, it was due to some abnormal condition. Falk secured no action on *Mycobacterium tuberculosis*. Kurloff and Wagner⁶⁵ noticed a selective action of the gastric juice. Cholera vibrio, *Eberthella typhosa*, and *Pseudomonas aeruginosa* (*Pseudomonas pyocyaneus*) were destroyed, but *Mycobacterium tuberculosis*, *B. anthracis*, and *Clostridium tetani* (spores) were not affected. Strauss and Wurtz⁶⁶ showed that anthrax bacilli were killed in 15 minutes, and that the destructive factor in the gastric juice was the hydrochloric acid. The same conclusion was reached by Kabrhel.⁶⁷ Hamburger⁶⁸ first called attention to the fact that some of the acid was bound and that the free acid had a stronger germicidal effect. This was proven by testing the action of a solution of HCl with one of the same strength containing peptone. Kianowsky⁶⁹ showed a direct relation between the number of bacteria in stomachs and the amount of acid. With patients possessing a faulty acid secretion many bacteria were found. Cadeac and Bournay⁷⁰ found that *Pseudomonas aeruginosa* (*Pseudomonas pyocyaneus*) was destroyed after six hours and that *Bacillus anthracis* and *Mycobacterium tuberculosis* were not killed. Pettenkofer⁷¹ reported some startling work which was carried out in 1893. This was done soon after the great epidemic of cholera in Hamburg and Altoona. He proposed the X, Y, Z theory for cholera where X = bacterium; Y = host or soil; Z = environment. He stated that X without Y and Z would not cause cholera. So thoroughly did these workers believe in this theory that Pettenkofer and Emmerich drank pure cultures of the cholera vibrio. Each mixed 1 ml. of a broth culture with 100 ml. of 1 per cent sodium bicarbonate solution and drank it. Pettenkofer did not change his usual manner of living and, after having diarrhea for four days, came back to normal. Emmerich's case ran a longer time. In this case the sodium bicarbonate neutralized the HCl of the gastric juice. The bacteria thus passed through the stomach and produced the usual results.

Stern⁷² did not regard the gastric juice as such a barrier against bacterial invasion as some of the former workers. He regarded persons with

hyperacidity as fortunate from this standpoint, but in no way absolutely protected. Bile was found to decrease the bactericidal action of the gastric juice. When proteins were present, cholera vibrios were found to live a long time. Pepsin was found to strengthen the action of the acid. Hansen⁷³ infected food with *Escherichia coli* and secured only a slight decrease of bacteria in the stomach. Schultz-Schultzenstein⁷⁴ found the gastric juice to be more germicidal than hydrochloric acid solution of the same strength. Gregersen⁷⁵ reported some of the more recent work on this subject. He studied the action of the acid in the juice and whether any other factors were important. In general, he found that without free acid, bacteria in the stomach were not killed. As the amount of free hydrochloric acid increased, the time required for destruction of bacteria was reduced. Experiments by Bartle and Harkins⁷⁶ indicated no germicidal activity in concentrations of "free" hydrochloric acid below .04 per cent, but when .08 per cent was present a well-marked germicidal action was evident.

Hajos⁷⁷ studied the germicidal action of gastric juice under different conditions. The bactericidal power was believed to be due to the free hydrochloric acid. Normal gastric juice killed old cells of bacteria of the colon-typhoid group in about 15 minutes. Bacteria introduced into the stomach along with solid foods were killed more quickly than those coming into the stomach with liquid foods such as milk or water. Foods in the latter group pass out of the stomach more quickly than the solid foods. People with hypoacidity are more prone to intestinal infections. The work of Schönbauer⁷⁸ would indicate that the germicidal action of the gastric juice might be due to combined activity of both pepsin and hydrochloric acid. According to Kopeloff,⁷⁹ the bacterial content of the saliva has much significance in interpreting bacteriological data from the stomach. Kopeloff reported that the bacterial condition of the stomach at any time is dependent on the saliva swallowed previous to analysis. In a later paper, this same author stated that the stomach acted as a receptacle for bacteria and that it was not a focus of infection.

Aronovitch, Coleman, and Einhorn⁸⁰ used the Einhorn intestinal tube and were able to investigate the bacteria in the intestinal contents much more thoroughly than did others. They were able to secure material 135 inches from the lips. In this report, they confined their work to the stomach, duodenum, and jejunum. Using eight subjects, they secured the following data: In the stomach the number of viable organisms and spores was low with the exception of one case in which the spore count was high. The type of organism was not especially significant. Acid was usually formed in dextrose and milk. In the duodenum, 28 inches from the lips, the number of viable organisms and spores was uniformly small, although

there was a slight tendency to increase in numbers. The organisms expected were found. There appeared at this point a greater diversity of types than in the stomach. In the jejunal contents, the results on the various patients seemed to be a little more irregular. The numbers seemed to increase.

Data secured with *Mycobacterium tuberculosis* are especially interesting in this connection. Fernbach and Rullier⁸¹ mixed tuberculous sputum with gastric juice and, after incubation under controlled conditions, injected into guinea pigs. The animals which received the digested sputum did not develop tuberculosis, showing that the organisms were destroyed by elements in the gastric juice. The intestinal juice from a dog is not capable of digesting tubercle bacilli, according to Mylius and Sartorius.⁸² After 24 hours of contact, the bacilli are less easily stained. There was also a slight decrease in the Much granules. Similar conclusions were reached by Inkster and Gloyne.⁸³

Later work by Johnson and Arnold⁸⁴ showed that free acid in the stomachs of dogs destroyed bacteria. During periods of acid deficits, the number of living bacteria became quite large. Rawles and Chapman⁸⁵ found this to be the case with *Escherichia coli*. An excessive number of *Escherichia coli* were found in the feces of individuals suffering from achlorhydria. When there was even a trace of free hydrochloric acid in the stomach, coliform bacteria were greatly reduced.

Results of investigations just reported indicate that the gastric juice shows bactericidal properties for most bacteria. That it does not destroy all of them is indicated by the fact that pathogenic species, such as *Eberthella typhosa*, pass through to cause severe infections. Furthermore, it is conceivable that bacteria imbedded in food particles would be protected. Water passes through the stomach quickly and bacteria in it would thus survive. The gastric juice would also be so diluted that its acid would be too weak to destroy bacteria.

Germicidal Action of Intestinal Secretions. Many of the body fluids are known to possess definite germicidal properties. Investigations have also been carried out to determine whether there are germicidal properties connected with intestinal secretions or mucosa. Soli⁸⁶ reported experiments on rabbits which demonstrated a specific germicidal action of the intestinal epithelium. The germicidal action varied in intensity and in different parts of the intestines, being strongest in the jejunum. Schutz⁸⁷ placed *Pseudomonas aeruginosa* (*Bacillus pyocyaneus*) in the intestines of cats and observed a destruction of cells which was attributed to a germicidal action.

Mylius and Sartorius⁸² could observe no dissolution or digestion of *Mycobacterium tuberculosis* by normal duodenal fluid. After exposure to

duodenal fluid for 24 hours, the cells of *Mycobacterium tuberculosis* lost some of their ability to retain the stain which would indicate that the organisms were changed in some manner. Löwenberg⁸⁸ demonstrated a bactericidal action of duodenal secretion on *Eberthella typhosa* (*Bacterium typhosum*) and *Shigella dysenteriae* (*Bacterium dysenteriae*). Löwenberg claimed that the cells of these organisms might pass through the bowel so quickly that they would not be exposed to the action of the juices. Direct contact under conditions which obtained in their experiments, prompted Day and Gibbs⁸⁹ to report that fresh pancreatic juice killed bacteria tested, with exception of *Staphylococcus aureus*, in 48 hours. In only one instance was digestion of the cells observed. While *Mycobacterium tuberculosis* was killed by the pancreatic juice, no evidence of dissolution nor loss of acid fastness was observed. Pancreatic secretion secured directly from the pancreatic duct by aid of secretin was consistently sterile.

Arnold and Brodny³³ made an appendicular fistula in each experimental animal, and cultures of *Serratia marcescens* or *Pseudomonas aeruginosa* were administered by mouth in various excipients, such as a watery suspension of lampblack or buffered milk solutions. The time of arrival of these organisms in the caecum, their maximal concentration in this region, and their period of persistence were studied by the removal of samples of intestinal contents from the fistula at suitable intervals. Full protocols of the experiments were given. The following conclusions were reached: Bacteria introduced (in watery suspension) into the empty stomach of a dog, 12 to 18 hours after a meal, do not reach the caecum. Bacteria introduced with alkaline buffered milk reach the caecum in large numbers over a relatively long period of time. Bacteria introduced with acid buffered milk sometimes reach the caecum, but in small numbers and over a relatively short period of time. Bacteria introduced into the stomach in an acid buffered aqueous solution seldom reach the caecum. When suspended in alkaline buffered aqueous solution, the bacteria reach the caecum in almost the same concentration as in the original ingested suspension. The "auto-disinfecting" mechanism of the upper part of the small intestine is dependent upon the presence of acid buffered material in its contents. This reaction is insured in the healthy animal by normal gastric secretory function. When neutral or alkaline buffered material enters the duodenum, this bactericidal power is lost and the bacterial content of such material is passed into the caecum.

Arnold³² observed an auto-disinfecting process in the upper half or two-thirds of the small intestine that destroyed bacteria ingested and prevented the large intestinal flora from extending upwards. Arnold stated that certain changes in diet as well as climate could cause a loss of this bacteria-killing power. Arnold³² reported that when the hydrogen-ion concentration was between 5.5 and 6.5 a substance was produced which inhibited the growth of aerobic bacteria.

Relation of Bacteria to Life. This has been a much-debated question. Pasteur⁹⁰ believed that bacteria were essential for normal life. Nuttall and Thierfelder⁹¹ reared guinea pigs under aseptic conditions which had been delivered by Caesarian section. These increased in weight, but not as regularly as normal pigs. From these data, the authors concluded that bacteria were not necessary for normal development. Schotellius⁹² hatched chickens in a sterile environment and from the data which he secured concluded that chicks could not live in absence of bacteria. He stated also that sterilizing the grain may have destroyed some essential substance. He had no knowledge of vitamins. Levin⁹³ found the intestines of most Arctic animals completely sterile. He drew no conclusions, but his work is of interest on account of normal growth without bacteria. Metschnikoff⁹⁴ grew tadpoles on sterile bread and water and secured no transformation into frogs in either the sterile or unsterilized tadpoles. The non-sterile grew larger than the sterile. Portier⁹⁵ observed that larvae of certain Lepidoptera lived aseptically. Moro⁹⁶ confirmed the work of Schotellius, which has been mentioned above. He used turtles instead of chicks. Bogdanow⁹⁷ concluded that bacteria were necessary for normal development because sterile larvae of Diptera did not do as well as those kept in an unsterile environment. Wollman⁹⁸ criticized the work of Bogdanow, stating that his sterilization was carried out at too high a temperature. He concluded from work on flies that bacteria were not necessary for normal development. Cohendy⁹⁹ thought that the digestive processes could proceed without bacteria but that they aided digestion. Life was thought to be possible without bacteria but bacteria are not indispensable. Kuster removed a kid by Caesarian operation from the mother and maintained it in a sterile condition for 14 days.

Kianizine¹⁰⁰ produced data which he thought weakened the argument of Cohendy. With chickens, Kianizine believed that bacteria were of great aid in digestion. They carried on analytic and synthetic processes which were of much value to the host. Further work was reported in 1916 by the same author. He made guinea pigs breathe sterile air and eat sterile food and found that, even after a few days, they were greatly weakened. The bad results from the deprivation of bacteria was thought to be due to reduced oxidation and accumulation of leucomaines in the body. Loeb and Northrup¹⁰¹ attempted to determine the ability of flies to synthesize their body proteins without the aid of microorganisms. Larvae grown on sterile media (banana) did not do well, while those placed in a sterile yeast cul-

ture developed normally. It was thought that yeasts were essential for this species of fly, although the essential element could not be isolated.

It is difficult to appraise the results reported in these early publications. The question may always be raised as to whether they had sterile conditions in their experiments. It has also been suggested that their methods of sterilizing foods may have destroyed vitamins and that failure to observe normal development was due to this factor. There is always the indefiniteness of what is normal development and growth. Perhaps the more recent experiments by Reyniers ^{101a} will help to settle the question. He reared a *Macacus rhesus* monkey under sterile conditions for 30 days when an accident allowed the the animal to become infected with bacteria.

Number of Bacteria in Feces. Different investigators are not in agreement on this question. This may be due, in part, to different methods of analysis and to the variations in samples. The securing of concordant results is hardly to be expected. The data which are on hand vary from 5 to 50 per cent. Strassburger ¹⁰⁴ stated that one-third of the feces of an individual on a normal diet was bacteria. The quantity of daily dried bacterial wastes in adults was as follows:

- (a) Eight grams under normal conditions.
- (b) In dyspeptic intestinal conditions on an average of 14 grams and even as much as 20 grams.
- (c) In chronic constipation 5.5 grams and, at times, even as little as 2.6 grams.

The total number of bacteria eliminated by an individual in one day was believed by Strassburger to be 128,000,000,000. Among the determinations which have been made by different investigators are the following, collected by Mattill and Hawk. ¹⁰⁵

	Daily Excretion of Dry Bacteria grams	Pct. of Dry Bacteria
Strassburger.....	8.0	24.3
Berger and Tsuchiya.....	3.023	12.60
McNeal, Latzer, and Kerr.....	5.34	26.90
Mattill and Hawk.....	8.27	27.97
Sato.....	8.54	24.39
Schittenhelm and Tollens.....		42.00
Lissauer.....		8.67
Tobaya.....		11.22

Osborne and Mendel ¹⁰⁶ found that about 70 per cent of the nitrogen in feces of animals was caused by bacteria. MacNeal, Latzer, and Kerr ¹⁰⁷ found most of the bacteria to be dead; the relative number of viable bacteria in human feces to the total count was estimated to be 1 to 3,000.

Vitamin Synthesis by Intestinal Microorganisms. If intestinal microorganisms are able to synthesize vitamins in the intestinal tract, the animal has an additional source of these necessary agents. This subject has interested microbiologists since the early days of vitamin investigations. Pacini and Russell¹⁰⁸ discovered from observations of clinical observers that in certain infections growth was produced apparently by the infection. In typhoid fever, for instance, the patient might grow one to even several inches in height. Pacini and Russell then stated that this increase in height might be due to the formation of accessory substances by the bacteria. The experimental data were interpreted to prove this contention. Rats on a deficient diet were given typhoid bacilli extract immediately after which there was a gain in weight. Development of scurvy in guinea pigs on a ration of heated oats plus 200 ml. of sterilized milk inoculated 48 hours before with *Lactobacillus bulgaricus* was thought to indicate, according to Wollman,¹⁰⁹ that the organism did not synthesize vitamin C. Similarly, development of polyneuritis in pigeons on a diet of sterilized rice inoculated with "Amylomucor" was also thought to indicate that this mold did not synthesize vitamin B. Evidence was found by Fulmer and his colleagues¹¹⁰ that bakers' yeast synthesized vitamin B. Addition of two per cent of the yeast grown on a synthetic ration proved sufficient to promote rapid growth in animals declining on the basal ration. About this same time Damon¹¹¹ observed no synthesis of vitamin B by *Salmonella schottmülleri*, *Escherichia coli*, or *Bacillus subtilis*. Administration of sterilized cultures of these bacteria as the sole source of vitamin B to rats on an otherwise adequate diet, did not stop a continued loss of weight. Further work with *Bacillus adherens*, Friedländer's bacillus, Pfeiffer's bacillus, *Bacillus ramosus capsulatus*, and the "timothy grass bacillus" yielded negative results with exception of Pfeiffer's bacillus and the "timothy grass bacillus," both of which, in amounts equivalent to five per cent of the diet, caused resumption of growth or maintained the animals at constant weight. Three members of the acid-fast group were found to produce vitamin B. Harden and Zilva¹¹² reported that yeasts grown on synthetic media contain vitamin B but not in as large amounts as those grown on wort. Scheunert and Schieblich¹¹³ observed formation of vitamin B by *Bacillus vulgatus*. Prompt increase in body weight and elevation of temperature to normal of pigeons in a state of nutritive decline when cultures of *Bacillus vulgatus* were fed, were thought to indicate synthesis of vitamin B. Similar observations were made by Zajdel and Funk¹¹⁴ and Sunderlin and Werkman¹¹⁵ using various common bacteria and yeasts which would

be found in the intestinal tract. Results of experiments by Schiebllich¹¹⁶ showed the importance of the culture medium in experimental work on this subject. Vitamin D synthesis by *Azotobacter chroococcum* was observed by Greaves.¹¹⁷ Similar observations were made for *Clostridium butyricum* and *Staphylococcus albus* but not for *Mycobacterium tuberculosis*, *Escherichia coli*, and a *Corynebacterium*, which contained neither sterol nor vitamin D. Several common species of bacteria were reported by Burkholder and McVeigh² to produce biotin, riboflavin, thiamine, and niacin in a synthetic medium. Microbiological methods of assay were used. They used *Escherichia coli*, *Proteus vulgaris*, *Aerobacter aerogenes*, *Alcaligines fecalis*, *Bacillus mesentericus*, and *Bacillus vulgatus*. The quantity of vitamins formed was small and they were contained in the bacterial cell. If this is shown to be the case, a logical argument is available for showing that intestinal bacteria are beneficial, if not necessary for the animal.

Destruction of Vitamins by Intestinal Microorganisms. Another important aspect of intestinal microbiology is the action of microorganisms on vitamins. Much effort is expended to determine vitamin contents of various foods and the effects of processing procedures on them. These foods are fed to animals with the general assumption that, with the help of control animals, some idea may be secured as to the effects of vitamins in foods on development and growth. Complicating this work is the possible effects of intestinal microorganisms, some of which have been shown to decompose vitamins in the intestines. While most of the work has been done with ascorbic acid, it is possible that microorganisms act on other vitamins. This situation is a little confused at the present time probably on account of the fact that not all species act on vitamins in the same manner. Consequently variable results would be expected. They would be determined by the species present in the intestines. Young and James^{117a} observed that two intestinal species *Escherichia coli* and *Aerobacter aerogenes* decomposed vitamin C under both aerobic and anaerobic conditions. Members of the genera *Alcaligines* and *Proteus* failed to attack the vitamin and produced a substance which protected the vitamin from atmospheric oxidation, but this substance did not function in the presence of vitamin C decomposing bacteria. Glucose and lactose in the nutrient medium also "spared" the vitamin from oxidation by fecal cultures and pure cultures of *Escherichia coli*. The vitamin disappeared from the medium as soon as the sugar had been used. Earlier investigations had shown that bacteria might decompose ascorbic acid, some of which were reviewed by Young and James. Esselen,^{117b} on the other hand, had stated that he could find no evidence which would indicate that bacteria are destructive of ascorbic acid and that loss of this factor in food could not be attributed to bacterial action. Esselen based his conclusions on results of an investigation in which 45 different strains, representing 39 species, were used.

Action of Bile on Bacteria. This juice is poured into the intestine just below the pylorus. It is a thick liquid with a decidedly bitter taste. It is made up of salts of glycocholic and taurocholic acids, pigments (bilirubin, biliverdin, etc.), fats, phosphatids, and inorganic salts.

The bile, like most of the other body fluids, is probably sterile when secreted. Toida¹¹⁸ found that bile of man and dogs was normally sterile, and that it was not a satisfactory medium for all bacteria. It was only slightly suited to *Staphylococcus pyogenes aureus* and *Pseudomonas aeruginosa* (*Ps. pyocyaneus*). *Streptococcus pyogenes* and *Dip. pneumoniae* were better adapted to it. The bactericidal action was found to vary with the origin. Just below the point of entrance into the intestine, the bacterial flora is much simpler. *Escherichia coli* is often the predominating form.

The regulation of carbohydrate fermentation by bile has been studied by Roger.¹¹⁹ The hydrolysis of starch was increased up to 30-40 per cent, but when smaller amounts (10 per cent) were used there was a retardation. Heating the bile did not destroy its activity. Moderate amounts of bile (5-20 parts per 100) retarded the action of intestinal bacteria on glycogen. Larger amounts were erratic, causing sometimes a retardation and sometimes an increase in the action. The same was found to be true with regard to glucose. Pure cultures of *Escherichia coli* were inhibited in their action on glucose, moderate amounts exerting a more consistent retarding effect than larger amounts.

Bile also exerts a retarding effect on putrefaction. Roger¹²⁰ found that the intensity of the biuret reaction of protein media inoculated with intestinal bacteria in the presence of different amounts of bile, showed that the attack on proteins was retarded. This retardation was evident up to concentration of 20 per cent, after which the retardation decreases. Roger¹²¹ regarded the bile as a factor tending to diminish the production of bacterial enzymes and neutralizing toxins. Boudiellé¹²¹ reported that bile, as well as bile salts, had an inhibiting action on the fermenting power of *Escherichia coli* on glucose. Moderate amounts had more pronounced effects than greater amounts. Lagane¹²² added bile to bouillon cultures and noticed no retardation in growth of intestinal bacteria. He claimed that it favored the development of *Escherichia coli* at the expense of other species.

Whether the bile is a germicide seems hardly to have been settled. However, most of the data which have been accumulated seem to show that bile exerts a selective action. Toida found that under normal conditions the bile was sterile. In this connection, it is interesting to remember that gall stones may be started by bacteria and that very often typhoid carriers liberate the bacilli in the bile. In these instances the bile seems to exert no bactericidal action, but perhaps a selective action.

Bile was shown to have a dissolving action upon pneumococci by Nicolle and Adil-Bey,¹²³ and earlier by Neufeld. Sodium choleate, the bile salts, and other similar preparations were also found to possess the same action. Farnet¹²⁴ reported that fresh bile dissolved typhoid bacilli and Marbais¹²⁵ stated that the disappearance of dysentery bacilli from stools of patients was closely correlated with the flow of bile into the intestinal tract. These were regarded as having been destroyed by the bile. To test this Marbais inoculated ox bile which had been heated to 120°C. (248°F.) with different strains of dysentery bacilli. Even 48 hours in contact with the bile failed to kill the bacilli. Van der Reis¹²⁶ found bile collected from diseased persons and animals very soon after death to be sterile. A bactericidal action of bile on the pneumococcus and *Bacterium putrificans* was found. *Streptococcus pyogenes* was also inhibited while *Escherichia coli* (*Bacterium coli*) and *Salmonella schottmülleri* (*Bacterium paratyphosum B*) seemed to be favored. Less favorable results were secured with *Serratia marcescens* (*Bacillus prodigiosus*), *Bacterium dysenteriae*, Flexner, the enterococcus and *Eberthella dysenteriae* (*Bacterium dysenteriae*) Shiga-Kruse. Knorr,¹²⁷ however, found a somewhat destructive action on the Shiga-Kruse type of *Salmonella dysenteriae* (*Bacterium dysenteriae*). A small inoculation was generally destroyed, while a heavy inoculation was able to survive and develop. Type Y of the pseudodysentery bacilli was found to resist, which perhaps explains why this organism is so frequently found in the feces. This subject has also been discussed at other places in this book, especially in Chapter 4.

Autointoxication. This has been one of the most interesting subjects in connection with intestinal bacteriology. The term autointoxication was introduced to signify the ill effects following an undue amount of putrefaction in the intestines. Proteins were split to compounds which would diffuse into the blood and cause headache, malaise, and, indirectly, according to Metschnikoff, senility. This latter investigator, who proposed his well-known sour milk therapy, believed that these protein-split products were at the foundation of premature death. This has been referred to again in the chapter on Fermented Milk Products. Very interesting, in this relation, is the paper of Alvarez,¹²⁸ in which it is claimed that this so-called "autointoxication" is used as a refuge for "etiologic uncertainty"—the same idea which Jordan has expressed with regard to "ptomaine poisoning." Alvarez claimed that there is little evidence to support the theory of intestinal toxemia. A complete review of the subject was prepared by Alvarez¹²⁹ in 1924.

Proteins are decomposed in the intestines by putrefaction into their constituent amino acids, which are, in turn, decomposed according to well-known chemical processes. The amino acids are decomposed by deaminiza-

tion, decarboxylation, and oxidation. Some of them yield end-products which must be detoxified before excretion. The indican reaction is probably the best known for determining the presence of intestinal putrefaction, although Bergeim³⁸ suggested another method.

Changes in Bacterial Content of Stored Normal Feces. These changes may be of considerable importance in diagnostic work involving examination of stools. As far as normal feces is concerned, Jordan¹³⁰ found that the number of bacteria increases during the first few days of storage. He further observed a decline in numbers after two weeks, although this decline was not universal. The actual number after two or three months' storage was often less than the initial number in the fresh stool, but this was not always the case; in more than one-third of the experiments the colony count was higher at the end of the storage period than at the beginning. The initial changes were followed. Increase in numbers was found to be due almost entirely to an increase in numbers of *Escherichia coli* (*Bacterium coli*). This increase was often enormous, amounting to two to three hundred times the original number. Jordan observed these changes at wide limits of temperature: 37, 20, and 10°C. (98.6, 68, and 50°F.).

Attention was also given to the longevity of *Eberthella typhosa* (*Bacterium typhosum*), since it had never been studied with modern methods. He found considerable difference in the longevity of *Eberthella typhosa* on different stools. The longest survival period observed by Jordan seems to have been 62 days. This is decidedly longer than that reported by previous investigators.

BACTERIAL STUDY OF FECAL MATERIAL

Specimens of feces for bacteriological examination should be collected in wide-mouth bottles and taken to the laboratory as soon as possible. Marked changes in temperature should be avoided.

Torrey's Technic for the Bacteriological Examination of Fecal Material. The following technic was devised by Torrey¹³¹ for the general study of the intestinal flora. His description is quoted:

PRELIMINARY PROCEDURE

Clinical Material. This should be examined as soon as possible after collection, certainly within two or three hours. The manner of obtaining the material is dependent on the purpose in view. If a bacterial analysis of the rectal region is desired a normal movement may be examined or the material obtained through the aid of a proctoscope, with or without a preliminary catharsis and irrigation, but if that from higher colonic levels is required, some such cathartic agent as epsom salts, phenolphthalein, or citrate of magnesia should be given and the specimen selected from the second or third movements, or better still from the result of a high irrigation with sterile water. Particularly, in cases of colitis it is important to obtain some mucus. This should be well washed in sterile salt solution and part spread on a slide for staining and microscopic examination and part streaked on the purple agar plate medium. (See Chapter 27.) If an examination of material from intestinal segments removed at operation is to be made, some of the lumen content is collected and with it scrapings from the gut wall. This

130. Jordan. 1926. J. Infect. Dis., 38, 306.

131. Torrey. 1926. Idem 39, 352-369.

should be placed in test tubes with rubber stopper and packed in ice prior to examination.

Reaction. The reaction of the material may readily be ascertained by the use of weak, aqueous (neutral) dilutions of the Clark and Lubs indicators, brom-cresol purple, brom-thymol blue or phenol red, according as the reaction is acid, nearly neutral or alkaline. A little of the material, about the size of a pea, is picked up on a glass rod or inoculation loop and rubbed into suspension in a tube containing about 10 ml. of the proper indicator and, after standing for a few minutes to allow for settling or after centrifuging, the color obtained is compared with known H-ion standards. This test should be made as soon as possible after the collection of the specimen.

Preparation of Fecal Suspensions. In order that an examination may have comparative value as regards quantitative bacterial findings, it is necessary to adopt some standard for the degree of density of the primary fecal suspension. The use of a nephelometer of the McFarland type, as recommended by Rettger and Cheplin, has its advantages, but as this or a similar instrument is not generally available, the following simple procedure is recommended and is believed to be sufficiently accurate for the purpose in view:

A small amount of the well-mixed fecal specimen taken up on a glass rod with a small prong at the end, is evenly suspended in about 20 ml. of salt solution in a test tube with an inside diameter of 16 and 17 mm. This is allowed to stand for several minutes to permit the coarse particles to settle and is decanted into another similar tube. A heavy mark with a wax pencil (black preferable) is then made about half way up on the outside of the tube and the density of the suspension adjusted, either by rubbing up more material or by adding salt solution until the mark is just discernible as a faint shadow in looking through the tube toward a strong light. This is labeled tube 1 and from it dilutions are prepared in a series of eight tubes, each containing 9 ml. of salt solution and 1 ml. of the preceding dilution. Tube 9 contains accordingly a 1:100,000,000 dilution of the primary suspension in tube 1. If the latter has been properly prepared, tube 3 will show only a faint cloud, just discernible when viewed in a good light against a dark surface. In the examination of material from the small intestine, the primary suspension is generally much lighter—about equal to the density of tube 2 of the above series.

Five ml. are next removed from each of the dilutions 1, 3, 5, 7, and 9 and are placed in narrow (10 mm. inside diameter) tubes. These are heated in a water bath at 80°C. (176°F.) for 10 minutes, thereby killing all but the strong heat-resistant organisms (chiefly sporebearers, although some streptococcal and *B. aerogenes* types may survive).

Microscopical Examination. Except for special purposes, such as the examination of infant stools, of material from different segments of the intestine, and following the degree of implantation of *B. acidophilus*, gram-stained films of fecal material generally give little or no definite information and may be omitted. If carried out, one of the alkaline modification of the original gram method such as that of Kopeloff and Beerman is recommended. This technic gives a much sharper differentiation than the original method. Mucus spread thinly on slides and air dried, may be stained with this method, with carbol thionin (Lyon-Smith), or with a tubercle bacillus stain, if such a procedure seems called for.

CULTURAL PROCEDURES

Brom-Cresol Purple Lactose Agar. The preparation of this medium has been described in Chapter 26.¹³²

Large petri dishes (120 mm. in diameter) are used and plates prepared with the above medium. At least three are desirable for an examination and after the agar has cooled and hardened they are surface-seeded respectively with a large loop (.4 cm. in diameter) of fecal suspensions in tubes 4, 3, and 2. The loop of material should be drawn across one side of the plate and then distributed thoroughly over the whole surface of the medium. If after seeding there is any evidence of moisture on the medium

132. Torrey stated that the Difco brand could be used if desired but that the reaction should be adjusted to pH 7.4; he also stated that the medium prepared from fresh meat gave a better differentiation as well as a greater variety of bacterial types.

surface, it should be dried off by partial uncovering and exposing the plate face downward in the incubator for a few minutes.

These plates are incubated for 24 to 48 hours at 37°C. (98.6°F.) and then kept at room temperature for two to three days longer for further study. *Staphylococcus aureus* colonies are particularly conspicuous after this period. They bring to development practically all of the aerobic types in the flora and nothing is to be gained by enrichment with ascitic fluid or a similar agent. This medium has marked differential value and if seeded in accordance with the above directions these plates give quantitative information as well. The *B. coli-aerogenes* group develop as yellowish colonies with a yellow zone. *B. mucosus* forms mucoid colonies with color unchanged or slightly yellowish; *B. typhosus* and *B. dysenteriae* colonies, thin, translucent, smoky hue, with medium unchanged; *B. paratyphosus* (intermediate) group like *B. typhosus* or medium darker purple with blue centers in colonies (*B. morgani*, *B. alkaligenes*); *B. proteus*, irregular spreading contours, dark reddish purple zone; *B. pyocyaneus* group, yellow colonies with greenish purple zone. For a general analysis of the flora for specific purposes representative colonies may conveniently be fished and seeded on Russell double agar slants and then carried through differential mediums. A great variety of coccus types develop on these plates. These may be differentiated by fishing representative type colonies and streaking on plain blood agar plates (pH 7.4). The effect on the blood agar, chromogenesis, morphology, and reaction to the gram stain, seeding into differential sugars (lactose, sucrose, salicin, raffinose, and mannitol) and into litmus milk and gelatin stab will generally serve for identification.

Virulence tests for *E. coli* or *B. paratyphosus*-like types may be made by seeding into meat infusion peptone broth (pH 7.0) and incubating for 24 hours. Dilutions of the cultures are made in sterile salt solution to 1:15 and 1:50. Two white mice (20 to 25 gm.) are then inoculated intraperitoneally, one with .5 ml. of the 1:15 and the other with .5 ml. of the 1:50 dilution. As regards the colon types, if the strain is avirulent neither will die, if moderately virulent the first, but not the second, will die within 48 hours, and if exceptionally so, both mice will die within that period. After inoculation with paratyphoid-like types the mice should be observed for four or five days to cover a more prolonged incubation period.

Reduced Oxygen Tension Plates. The medium for these plates is nutrient glucose agar (meat or liver infusion, 1 per cent peptone, 1.5 per cent agar, .5 per cent glucose, (pH 7.4) to which 10 per cent fresh, defibrinated, sterile blood has been added just before the plates are poured. Deep petri dishes (20 mm.) should preferably be used. Oxygen tension reduction is obtained by *B. subtilis* growth on an opposed agar plate in accordance with the technic recently described by Herrold¹³³ for gonococcus culture. This was in turn a modification of a method described¹³⁴ some years ago in which the Wherry and Oliver technic¹³⁵ was adapted to plate cultures.

Two sterile bottoms of deep petri dishes are selected which are exactly of a size. Into one the blood agar medium is poured and when hard is surface-seeded with diluted fecal suspension, drying off, by inverting in the incubator, any obvious surface moisture after seeding. Into the other dish about 10 ml. of a firm nutrient agar, seeded with *B. subtilis* (a type producing a thick growth, such as *B. cereus*, is preferable) is poured. When hard it should be dried off in the incubator until no moisture is visible. These two bottoms are then fitted together and bound with 1-inch wide adhesive tape, and this in turn is covered with broad elastic bands.

One blood plate should be surface-seeded with a large loop (4 mm. diameter) from dilution tube 4, and one from dilution tube 3. They should be incubated for at least 48 hours with the blood agar side uppermost. This method will at times bring to development a surprisingly large variety of organisms, some of which have not been recovered in any other way. *B. bifidus* and *B. acidophilus*, grow particularly well and may be recognized by the brown or chocolate color and morphology of the colonies. At times

133. Herrold. 1921. J. Amer. Med. Assoc., 76, 225.

134. Torrey. 1917. J. Bact., 2, 435.

135. Wherry and Oliver. 1916. J. Bact., 19, 288.

the colony count for these plates is many times that for aerobic plates seeded from the same fecal dilution and on the same medium.

Cooked Meat Medium. This medium is prepared according to the original description by Robertson,¹³⁶ except that peptone is added and the reaction adjusted to pH 7.2.

Just before seeding, the seven tubes necessary for the examination are placed in the Arnold for 15 minutes and then cooled to 45°C.(113°F.). One tube is next seeded with 1 ml. of unheated dilution 5 of the specimen, placing the tip of the pipette rather deep in the meat, and one tube with 1 ml. of the unheated suspension 1. Five other tubes are seeded respectively with 1 ml. from dilutions 9, 7, 5, 3, and 1, heated at 80°C.(176°F.). The height of the meat column in each tube is then registered by a wax pencil mark on the glass, and all are capped by running about 5 ml. of melted, warm, sterile, yellow vaseline on the surface of the fluid in each tube. They are then incubated at 37°C.(98.6°F.) and are examined after 1, 3, and 6 or 7 days. At each observation the degree of digestion is measured in millimeters as shown by the decrease in the meat column height, the amount of gas noted (elevation of the vaseline cap) and also changes which may have occurred in the color and composition of the meat as indicated in the table. The tube seeded with the unheated fecal suspension 1 yields information particularly in reference to the putrefactive propensities of the whole flora. If the decrease in the meat column height amounts within a week to 1.5 to 2 cm. an unusually marked putrefactive propensity is indicated; if between 1 and 1.5 cm. a fairly marked; and less than 1 cm. a moderate to slight tendency. The digestion is very largely due to the sporebearing anaerobes.

Microscopic Examination of the Feces. Direct microscopic examination of the feces may give valuable information on the microbiological relationships in the intestines. Iodophile bacteria are colored blue with iodine.

Methods for Determining the Number of Bacteria in Feces. There are many factors which complicate such determinations. The accurate enumeration is not easy and consequently, a number of different methods have been proposed. It is difficult to separate the bacteria from the other material in feces, and this complicates the counting of the bacteria by either the microscope or chemical methods. Plating out on agar or gelatin would be inadequate. Only living bacteria could be counted and several types of plates would have to be prepared in order to count both the aerobic and anaerobic forms.

MacNeal's (et al.) Modification of the Winterberg Method. The first employment of the Thoma-Zeiss blood-counting chamber for bacteriological technic was made in the one-cell dilution method of obtaining a pure culture. By this method the number of cells per unit volume could be ascertained and the dilution per unit volume of a suspension with one cell in two to five drops required to obtain a suspension with one cell in two to five drops calculated. In this way the first pure bacterial culture was obtained. Henrich Winterberg was the first to use this method of bacterial counting, and to test its accuracy both as regards suspensions of varying dilutions and in comparison with the microscopic plate-counting method. He considers the method more accurate than the plate-counting method, but as a quantitative procedure he would consider it unimportant. He says his determinations were too low. Winterberg's counts were made with suspensions of living bacteria in bacteria-free distilled water.

The method, as used by MacNeal, Latzer, and Kerr, is as follows: a portion of the 1:100 suspension of feces is diluted 10 times, and a portion of this is drawn up to the mark 1 in the capillary of a dilution pipette, ordinarily used in estimating the white blood cells. This is diluted to the mark 11 with a dilute solution of methylene blue in physiological-salt solution. (The staining solution consists of methylene blue, 1 gm.; glycerine, 25 ml.; distilled water, 75 ml. A few drops of this are mixed with

136. Robertson. 1916. J. Path. and Bact., 20, 327.

10 ml. of .8 per cent salt solution until the mixture is well colored, but not too opaque. This mixture is used as the diluting fluid. A little practice will show the proper depth of color to be employed.) The suspension is thoroughly mixed in the bulb by shaking and rolling in the usual manner. Several drops are blown out and then a very small drop is placed in the center of the circular elevated portion of the slide, which has been previously thoroughly cleansed by washing in distilled water and alcohol. A clean, thin, ground cover slip is made slightly moist by breathing upon it and is immediately placed upon the slide. Slight pressure upon it causes the Newton color rings to appear, and these remain after the pressure is removed, if the preparation has been properly made. The slide is allowed to stand one to two hours to allow the bacteria to settle. Then the bacteria in 50 small squares upon the scale are counted microscopically, the No. 7 Leitz objective and No. 3 ocular being used. The calculation is simple as an example will show:

“Example. B252, Subject H, July 15, 1908. Fifty squares contain 400 bacteria. Therefore the average per square is 8.0 bacteria. One small square = $1/4000$ c.mn. One c.mn. contains $8 \times 4000 = 32,000$ bacteria. One milliliter contains $32,000 \times 1000 = 32,000,000$ bacteria. Pipette dilution is 1:10. $32,000,000 \times 10 = 320,000,000$ bacteria per milliliter of 1/1000 suspension. One milliliter of 1/1000 suspension is equivalent to 1 mg. feces. Therefore, there are 320,000,000 bacteria per milligram feces.

“Counting by this method is an exacting process and much practice is required to see all the bacteria present. Careful adjustment of the light is important and best results have been obtained by illumination with Welsbach light; constant focusing through the different layers is necessary. Perhaps the greatest source of error is the difficulty of distinguishing accurately the bacteria. Skill in this is acquired only by practice. The method has the advantage of simplicity. The results of the authors seem to conform to those of Winterberg in that high dilutions give a relatively high count.”

MacNeal's (et al.)¹⁰⁷ Modification of the Eberle-Klein Method for Determining the Number of Bacteria in Feces. Eberle, working in Escherich's laboratory, was the first to determine the quantity of fecal bacteria by counting them in stained films. His experiments were carried out with normal infants' stools. Cover-glass preparations were made from fecal suspensions of known dilution and, after being completely dried, were stained with freshly prepared aniline water fuchsin, then washed in water, air-dried, mounted in Canada balsam, and counted. The method was very much improved by Alex. Klein, and Hehewerth. Klein had noticed that vegetative bacteria were more sensitive to disinfectants in a moist than a dry state, and this led him to believe that bacteria would also be stained more readily in a moist condition than after drying. Therefore, he allowed the dye to act while the bacteria were suspended in a liquid and the cover-glass preparation was made, dried, and fixed, only after the bacteria were stained. Later the same investigator modified the method still further, using gelatin to fix the stained bacteria to the cover glass. The aqueous solution of gelatin and the stained bacterial emulsion were put upon the cover-glass separately, then fixed and spread. When dry, the preparation was immediately mounted in Canada balsam without flaming.

The procedures as employed by MacNeal, Latzer, and Kerr have been considerably modified. In the addition of the gelatin to the bacterial suspension, in spreading the films, in selecting the fields to be counted, and in counting individuals, rather than groups, as units, the technic differs from Klein's method. Of the 1:100 suspension of the feces prepared as described above, $2\frac{1}{2}$ ml. are transferred to a clean, dry bottle. $\frac{1}{2}$ ml. of melted nutrient gelatin and 2 ml. of aniline water gentian violet added, and the whole thoroughly mixed and allowed to stand for three to five minutes. Then by means of a platinum loop, the carrying capacity of which has been determined with great care, a loopful of the mixture, well shaken, immediately before, is transferred to a clean, flamed 20 mm. square No. 1 cover glass and deposited near the center of the glass. Immediately another cover glass of the same size is accurately placed on top of the first so that the two glasses are in contact over about three-quarters of their surfaces and the sides evenly fitted together. As soon as the liquid has spread evenly between the two cover glasses, they are quickly slipped apart and allowed to dry. The technic

here is the same as ordinarily used in the preparation of cover glass blood films. If the preparation does not appear evenly spread, the process is to be repeated with two or more cover glasses until a satisfactory result is obtained. The films are next accurately measured by a millimeter rule and then, without further treatment, mounted in Canada balsam upon one slide so that one diagonal of each rectangular film is parallel with the long axis of the slide. By laying the slide over the coordinate paper these diagonals are readily brought into the same line parallel with the edge of the slide.

The covers must be so mounted that these diagonals, now in a straight line, are those which crossed each other as the two cover glasses were originally put together in preparing the films. When properly made, each diagonal measures almost exactly 25 mm.

For counting the bacteria in the preparation, the Leitz 1/12 oil immersion objective and the No. 3 ocular fitted with an Ehrlich ocular square to restrict the field to a convenient size and a mechanical stage graduated in millimeters are employed. Beginning at the end of the diagonal of one cover glass the bacteria are counted in each of 25 fields 1 mm. apart along this diagonal. In a similar way 25 fields are counted on the diagonal of the second cover glass., making a total of 50 fields, the average of which may be considered as representative of both films. The size of the square field is accurately measured by a stage micrometer. From the data then at hand, the number of bacteria per milligram feces is calculated.

“Example. B252, Subject H, July 15, 1908. In the preparation made, as described, each film measures 16.5 × 17.55 mm., total film area therefore, 33 × 17.5 mm.; the field employed measured 0.0445 mm. square; the amount carried by the loop 2.01 mg.; the number of bacteria counted in 50 fields was 559 and the original 1:100 suspension was used (diluted to 1:200 by dye and gelatin). From these data, Bacteria per milli-

$$\text{gram feces} = \frac{559 \times 33 \times 17.5 \times 200}{50 \times 0.0445 \times 0.0445 \times 2.01} = 324,000,000. \text{ In this fraction all the mem-}$$

bers except the size of the films and the number of bacteria counted may be kept constant and the calculation simplified by the use of logarithmic tables.

“With apparatus and reagents ready and the 1:100 suspension prepared, this entire estimation can be completed in about 40 minutes. The results cannot be considered very accurate as the platinum loop does not carry an exactly constant quantity. There is also sometimes great difficulty in distinguishing micrococci from other fine particles in the preparations. The concentration of the bacterial suspension also influences the final result. The estimation is in general relatively higher when dilute suspensions are counted as we have observed in applying it to enumeration of bacteria in pure cultures.”¹⁰⁷

Steele's Modification of the Strassburger Procedure for the Quantitative Enumeration of Fecal Bacteria. Steele described the method as follows: The possibility of separating the bacteria from the rest of the feces depends on the fact that the bacteria are so nearly of the same specific gravity as distilled water that they cannot be centrifugalized out of a watery suspension of the feces, but remain suspended in the supernatant fluid. Taking advantage of this, the bacteria can be removed by washing with the centrifuge. Then, if the specific gravity of the wash-water is lowered by the addition of large amounts of alcohol, the relation of the bacteria to the fluid is changed to such an extent that the microorganisms can be readily centrifugalized out, separated, and weighed. Unless the period of passage of the feces has been ascertained to be normal, it is better to mark the beginning and end of each period of examination by carmine. The end of the Schmidt diet is not necessary. The whole stool is saved. Unless the feces are liquid they are rubbed up with a known amount of distilled water until they are smooth and semiliquid and as homogeneous as it is possible to make them.

Two portions of 5 ml. are measured off with a pipette of large caliber, using for this purpose an ordinary 5-ml. pipette with the tapering end cut off, and with the necessary correction made at the upper mark. One of these portions of 5 ml. is put into a porcelain dish and dried over a water bath and later in a drying oven, in order

to determine the dried weight. The addition of a little alcohol and thorough mixing will hasten the process of drying and prevent caking of the feces.

The second portion is washed free from bacteria. This is done as follows: The wash-water is .5 to 1 per cent HCl solution in distilled water. The acid increases the solubility of the salts and soaps of the feces. One hundred ml. of this solution is employed at the beginning of the washing. The feces are thoroughly mixed with the wash solution and then centrifugalized. The use of the water motor or electric centrifuge is almost essential. Each tube is centrifugalized for about $1\frac{1}{2}$ minutes, then the cloudy supernatant liquid is poured through a layer of gauze. This fluid contains the bacteria in suspension. All of the mixture (the wash-water and the feces) is centrifugalized the same way, and then the residue in the tubes is shaken up with more of the wash-water and centrifugalized again. This is repeated until the supernatant liquid after the centrifugalizing is transparent, showing that approximately all the bacteria have been washed out. If a smear is made of the residue at this point, it will be found that the bacteria are not entirely washed away, but are evidently very much reduced. They occur singly, while in the unwashed feces they are in great lumps and masses. The suspension of bacteria is then mixed with a liberal portion of alcohol, and evaporated down slowly at a temperature of 40 to 50°C. (104 to 122°F.) until it amounts to not more than 50 ml. in all. This takes approximately 24 hours. It is then mixed with at least twice its volume of alcohol, preferably absolute alcohol, although this is not absolutely necessary. This lowers the specific gravity of the fluid to such an extent that now the bacteria readily centrifugalize out. The mixture is then centrifugalized until the supernatant liquid is quite clear. This takes 30 minutes or more for each tube. The residue, which consists of the bacteria, is washed with pure alcohol and is shaken up with ether to remove the fat; then it is again washed with alcohol. All of this washing is done by means of the centrifuge. The bacteria are next washed out of the tube with a little alcohol and evaporated to dryness and dried in the oven at moderate heat, dried in the desiccator, and weighed. Smears of the final preparation show that it consists of bacteria with a very few minute particles of other material. These particles are only visible with high power, and are very few in number, perhaps two at each field of the 1/12-inch objective. They stain with methylene blue; Strassburger suggests that they are cellulose, which they may well be. At any rate, the error arising from the inclusion of these small particles in the dried weight of the bacteria must be very small, and is probably balanced by the bacteria that it is not possible to wash out of the residue in the first washing. During the preparation of the bacteria the first portion of 5 ml. has been dried and weighed. We then know the dried weight of 5 ml., the weight of the dried bacteria in 5 ml., the original volume of the stool, and the volume after the addition of a known amount of water. It is then easy to calculate the data that we desire, namely the volume of the stool, its dried weight, the weight of the dried bacteria, and the percentage of bacteria in the dried weight.

Mattil and Hawk's¹⁰⁵ Method for Quantitative Determination of Fecal Bacteria. The method is a simplification of MacNeal's adaptation of the Strassburger procedure. About 2 grams of feces are accurately weighed and placed in a 50-ml. centrifuge tube. To the feces in the tube a few drops of .2 per cent hydrochloric acid are added, and the material is mixed to a smooth paste by means of a glass rod. Further amounts of the acid are added with continued crushing and stirring until the material is thoroughly suspended. The tube is then whirled in the centrifuge at high speed for one-half to one minute. The suspension is found sedimented in more or less definite layers, the uppermost of which is fairly free from larger particles. The upper and more liquid portion of the suspension is now drawn off by means of a pipette and transferred to a beaker. The sediment remaining in the tube is again rubbed up with a glass rod with the addition of further amounts of dilute acid, and again centrifugalized for one-half to one minute. The supernatant liquid is pipetted off and added to the first, the same pipette being used for the one determination throughout. A third portion of the dilute acid is then added to the sediment, which is again mixed by stirring and again centrifugalized. All the washings are added to the first one and, during the process, care is taken to wash the material from the wall and mouth of the centrifuge down into it.

Finally, when the sediment is sufficiently free from bacteria, the various remaining particles are visibly clean, and the supernatant liquid, after centrifugalization, remains almost clear. This is removed to the beaker in which are now practically all of the bacteria present in the original portion of feces, together with some solid matter not yet separated. In the centrifuge tubes there is a considerable amount of bacteria-free solid matter.

The suspension is now transferred to the same centrifuge tube, centrifugalized for a minute, and the supernatant liquid transferred to a clean beaker by means of the same pipette. The tube is then refilled from the first beaker and thus all the suspension centrifugalized a second time. The beaker is finally carefully washed with the aid of a rubber-tipped glass rod, the second sediment in the centrifuge tube is washed free of bacteria by means of this wash-water and the successive portions of the dilute acid, and the supernatant liquid, after centrifugalization, is added to the contents of the second beaker. The second clean sediment is added to the first. The bacterial suspension now in the second beaker is again centrifugalized in the same way and a third portion of bacteria-free sediment is separated. Frequently a fourth serial centrifugalization is performed—always if the third sediment is of appreciable quantity. At all stages of the separation, small portions of the dilute hydrochloric acid are used, so that the final suspension shall not be too voluminous. Ordinarily it amounts to 125 to 200 ml. At the same time, the final amount of fluid should not be too small, as shown by Ehrenpfordt, because the viscosity accompanying increased concentration prevents proper and complete sedimentation.

To the final bacterial suspension an equal volume of alcohol is added and the beaker set aside to concentrate. A water bath at 50 to 60°C. (122 to 140°F.) is very satisfactory. After two or three days, when the liquid is concentrated to about 50 ml., the beaker is removed and about 200 ml. of alcohol are added. The beaker is covered and allowed to stand at room temperature for 24 hours. At the end of this time the bacterial substance is generally settled, so that most of the clear supernatant liquid, of dark brown color, can be directly siphoned off without loss of solid matter. The remainder is then transferred to centrifuge tubes, centrifugalized, and the remaining clear liquid pipetted off. The sediment consists of the bodies of the bacteria, and is transferred to a Kjeldahl flask for nitrogen determination. This is the bacterial nitrogen. Where a determination of bacterial dry substance is desired, the sediment of bacteria is extracted by absolute alcohol and ether in succession, transferred to a weighed porcelain crucible, and dried at 102°C. (215.6°F.) to constant weight. This dried sample is then used in the nitrogen determination. Our procedure differs from that of MacNeal in that the bacterial dry matter is not determined. A saving of about seven days' time and of considerable labor is accomplished by this omission.

Inasmuch as it has been shown by various investigators that such bacteria as are present in the feces contain on the average about 11 per cent of nitrogen, the values for bacterial nitrogen as determined by our method may conveniently serve as a basis for the calculation of the actual output of bacterial substance.

CHAPTER 14

MICROBIOLOGY OF FRUITS AND FRUIT PRODUCTS

Fresh fruits may possess a varied flora of microorganisms, the number and types of which are determined by conditions under which fruits have been grown. Nature has provided many of them with protective coverings which shield the fruits from microbial decomposition as long as they are intact. Once the covering is broken, however, microorganisms enter readily. Presence of much acid and sugar in fruit juices makes them especially suitable for yeasts and molds.

Microorganisms on Fresh Fruits. Microorganisms on fresh fruits have a several-fold interest for food technologists. They may be spoilage organisms which must be destroyed in any preservation process to which the food may be subjected later, or they may be organisms which are desirable if the fruits or their juices are to be fermented. Lastly, they may be pathogenic and introduce health hazards later if the fruits are eaten raw and without washing or sterilization. Various investigators have reported results of investigations on the general flora of microorganisms present. As would be expected many different species and types are found. Some of the earlier work was carried out by Hansen,¹ Delbrück,² and others with grapes because it was necessary to know what effect the general flora might have on fermentation of the grape juice. Yeasts were reported by Hansen to be commonly present in the soil of vineyards where they spent the winter. While they were also found in the soil of beech and oak groves, they were not as common as in the soil of vineyards. They reached the grape by means of dust and insects. Smeall³ found various microorganisms on fruits. On dates which were in boxes from Iraq and Tunis *Bacillus subtilis* and allied species were found; about half of the samples showed streptococci. Yeasts were found on the grapes. Cherries had a general flora quite like that of the other fruits examined.

Mold spores are commonly prevalent on citrus fruits and are responsible for spoilage. Mechanical injury and spore loads, according to Tomkins,⁴ should be kept at a minimum. Molds are especially troublesome on citrus fruits on which they develop with ease when the resistance of the fruit is lowered owing to age or injury.

Microorganisms in Inner Structures of Fruits. Most information on microorganisms in fruits concerns the outside surface, for it is that area which would most likely be heavily contaminated. One or two investigators (Romwalter and Kiraly⁵) have reported presence of microorganisms in the inner structures of fruits, seeds, and plant tissue as well as in the sap. Similar results were reported by Niethammer.⁶

Presence and Survival of Pathogenic Bacteria on Fruits. Since many fruits are eaten without sterilization, experiments have been carried out to determine whether pathogenic bacteria could survive for significant periods. This subject is especially important in places where sanitation is not practiced or where night-soil may be used as a fertilizer. Numerous reports have also been published on the presence of pathogenic bacteria on fruits and their possible relationship to disease dissemination. Ehrlich,⁷ Abbott,⁸ Rommel,⁹ Ressel,¹⁰ Neumann,¹¹ Clauditz,¹² and Sartory and Fillasier,¹³ all reported that fruits may carry not only indicators of pollution but even pathogenic bacteria. The last-mentioned investigators studied fruits exposed for sale on Paris street stands and found that they carried a large number of organisms, the principal species being *Penicillium glaucum*, *Rhizopus nigricans*, *Staphylococcus aureus*, *Bacillus termo*, *Bacillus subtilis*, and *Micrococcus candicans*. Washing removed a large proportion of the bacteria; lower numbers were found in the second and third wash waters as compared with the first. The authors concluded that sale of fruits intended for consumption without cooking should be subject to regulation. Abbott⁸ found pathogenic bacteria and organisms of sanitary significance on grapes and berries exposed for sale on sidewalk stands. The danger of disease dissemination by raw fruits is probably not as great in America as it is in countries where the great epidemic diseases are rampant. Vasquet-Colet,¹⁴ who investigated the subject for three epidemic diseases, typhoid fever, cholera, and dysentery, found that *Vibrio comma* survived on human food for as long as six days.

Cholera epidemics in India have been related by Bharucha and Bharucha¹⁵ to consumption of watermelons. While the whole fruit was sterile, cut slices sold on the open market were contaminated with dust organisms. The maximum survival of the organism in artificially inoculated watermelon was six days. Growth appeared in watermelon juice as acid as pH 4.7.

The survival time for the etiologic agents of the other two diseases was not much different. Garcia¹⁶ reported the results of a short study of common fruits (apples, lemons, oranges, and bananas) since these fruits are usually eaten raw. *Escherichia coli* was always present. The Medical Officers of Health of Cardiff, Wales,¹⁷ have twice found *Bacillus anthracis* on hides bound around orange boxes shipped from Spain. This organism might thus reach the fruit. Johnston and Kaake¹⁸ found members of the colon-dysentery group on fresh fruits purchased on the Toronto market. These are generally accepted as the cause of summer diarrhea in

children and are therefore of some hygienic significance. *Shigella dysenteriae*, Sonne, artificially inoculated into a tomato, was recovered after two but not after six days and from apple after six but not after eight days. Further information on the longevity of pathogenic microorganisms on fruits was reported by McCleskey and Christopher¹⁹ whose experiments involved strawberries inoculated with aqueous suspensions of pathogenic bacteria just before freezing. Their results are given later in this chapter. Giuffrida²⁰ found no *Mycobacterium tuberculosis* on fruits. Such bacterial agents of disease are probably not as widespread in nature as those mentioned above.

The conditions which obtain on the surface of fruits are, apparently, not inimical to the organisms of typhoid fever and cholera. In addition to the facts quoted above are the conclusions of Murillo²¹ and Ko.²² The former sprayed fruits with cultures of *Vibrio comma* and *Eberthella typhosa*. Juice from half-ripe fruit exerted a stronger action than fully ripened fruit. The vegetable acids were ranked as follows in their action: tannic, citric, tartaric, and malic. Lemonades were decidedly germicidal. The juices from some oranges, mango, and watermelon were devoid of action. Alliot²³ confirmed these results for lemon juice and white wine. Under the conditions of his experiments the minimum time for lemon juice to kill *Eberthella typhosa* was 15 minutes; *Salmonella paratyphi*, 15 minutes; and *Salmonella schottmülleri*, 20 minutes. In this connection should be mentioned the experience of certain investigators that lemon juice in home-canned vegetables exerts a destructive action on *Clostridium botulinum* and its toxin. However, others have not confirmed this.

Morel and Rochaix²⁴ employed the thread method of Koch for studying the effect of certain vegetable essences on bacteria. The following essences were used: lemon, thyme, orange, bergamot, juniper, clove, citron, lavender, mint, eucalyptus, and several others. Threads impregnated with the above organisms in pure culture were suspended over three ml. of these essences in test tubes. The vapors from lemon, thyme and orange were most effective. A long contact was necessary. These results are in accord with that of Thöni,²⁵ who found that the bacterial content of fresh lemonade progressively decreased. Guyot²⁶ reported a viscous fermentation of this product.

Conn-Cholodny's Method for Microbiological Examination of Fruits and Vegetables During Storage. This procedure, developed for use in the field of soil microbiology, was adapted to examination of fruits by Shtrobindev and Driabina.²⁷ The surface of the fruit is first sterilized with alcohol and a cut is made with a sharp sterile knife through the section to be investigated, such as a spoiled portion surrounded by healthy tissue. A clean, sterile microscope slide is then inserted into the cut after first spreading the sides; the fruit is then pressed against the slide and the crack sealed with sterile

collodion. After incubation of the fruit for seven to 21 days, the slide is removed, dried, and stained. From examination under the microscope the type of microflora may be determined.

Washing and Disinfection of Fruits. While washing removes many microorganisms from the surface of fruits, it is frequently not enough. Sterilizing treatments may be desirable for destruction of harmful microorganisms. Champion and Van de Velde²⁸ studied especially the significance of *Escherichia coli*. Strawberries, lettuce, and carrots, when rinsed in .2-per cent solution of chloride of lime, were reasonably well disinfected. After exposure to this solution for 30 minutes, *Escherichia coli* was destroyed and the total number of bacteria greatly reduced. The organoleptic properties were not altered. Herfarth²⁹ placed fruits in a solution containing 4.5 grams of chloride of lime per liter and allowed the solution to act. With stronger solutions shorter times were required for sterilization. The disinfectant may be easily removed from the fruits by careful washing.

Many attempts have been made to rid apples of undesirable bacteria before pressing. Parville³⁰ used formaldehyde for this purpose, while Alliot and Gimel³¹ used chloride of lime.

The practice in the Orient of fertilizing the soil in which vegetables and fruits are grown with human excreta caused Mills, Bartlett, and Kessel³² to study the sanitary features of foods grown under such conditions. Several fruits and vegetables from the market were examined for sterility of the interior structures; all were found to be sterile. Fruits first sterilized in chlorine water and then immersed in broth containing *Escherichia coli* were found to have viable organisms on their surfaces after exposure for at least 15 days under dry or moist conditions. The bruised areas of fruits and the cut ends of vegetables after similar exposure contained viable organisms, but the main portions remained sterile. Attempts to sterilize fruit contaminated in this way were successful in the case of chlorine water, 10 parts per million for 15 minutes, and boiling water for 10 to 20 seconds, and were partially successful in the case of soap and water and chlorine water, three to six parts per million. Matsuoka and Shiraiwa,³³ when experimenting with the chlorine compounds as disinfectants for fruits, found that long times and too high concentrations were required when the fruits were cut up. However, the surfaces of apples were effectively sterilized by 30 minutes' exposure to a solution containing 50 p.p.m. of available chlorine. Lombardo³⁴ treated apples, pears, grapes, peaches, lettuce, celery, and fennel with various disinfectants for different lengths of times. Some were inoculated with pure cultures of *Eberthella typhosa*, *Vibrio colerae*, and *Salmonella* species. Satisfactory disinfection was secured with chlorinated lime (20.7 per cent available chlorine) after 30 minutes' treatment with a 1.5-per cent solu-

tion. Excess chlorine was removed by washing the fruits and vegetable in dilute sodium thiosulfate. Formalin was also satisfactory in five-per cent solution. After 30 to 40 minutes' treatment the materials were washed in clean water. Pathogenic microorganisms were destroyed, and taste and appearance were not changed. Chlorinated lime was also found to be satisfactory by Vendramini.³⁵ After treatment with one-per cent solution and rinsing in clean water, strawberries which had been soaked in a suspension of *Eberthella typhosa* were disinfected. Several different types of wine were also tested with unsatisfactory results. None of the wines sterilized the strawberries in 30 minutes and some failed to do so in three hours. There seemed to be little relation between the alcohol and acid content of the wine and disinfecting power. Lemon juice failed to sterilize the strawberries in one hour.

Hot water may also be used for disinfecting some fruits where slight changes caused by it are of no consequence. Ommyoji³⁶ stated that grapes suffered no deterioration by passage through water at 80°C. (176°F.), but the bacilli on them were killed; on pears with decayed spots, they were not killed.

Role of Sugar in Preservation of Fruits. Sugar sirups play a large role in fruit preservation. They not only bring out fruit flavors but inhibit development of microorganisms. When heat is also used most microorganisms are destroyed. In studying this, Bitting³⁷ observed no preservative effects of sugar until the amount of sugar had reached 25 grams per 100 ml. of bouillon. For studying the restraining action of sugar against mold, solutions were prepared containing amounts of sugar up to 200 grams per 100 ml. of bouillon. The growth of the molds became slower up to 17 grams per 100 ml. and above that amount it required two months to secure growth. Yeasts were not able to survive 80 grams of sugar in 100 ml. Barnard³⁸ studied the subject directly for fruits. First, sirups were prepared by both the hot and cold methods, containing 8, 10, 12, 14, and 16 pounds of sucrose per gallon of water. A few lots of the 10- and 12-pound sirups developed mold in a week. Then crushed fruits were prepared, for soda-fountain use, by adding one part of fruit to two parts of simple sirup. Barnard reported that fruits in sufficiently heavy sirups would keep for some time if kept cold. Experiments of a similar nature were made by Grove³⁹ on jams, jellies, and preserves. When 50 per cent sugar was present, yeasts and bacteria did not develop. In a 45-per cent concentration growth took place if the acidity was below .8 per cent, but was completely stopped when it was over 1.2 per cent. Addition of 1 per cent of salt also stopped the development of yeasts and bacteria. A sugar concentration of 65 per cent was required to stop the growth of *Penicillium glaucum*, and there was feeble growth after a month of

per cent concentration. Tarkow, Fellers, and Levine⁴⁰ observed more inhibitory action of glucose than sucrose in equal concentrations. Mixtures of these sugars showed an inhibitory action intermediate between that of each sugar when used alone. A greater number of sugars were studied by Erickson and Fabian.⁴¹ Their order of activity with the organisms used was fructose, dextrose, sucrose, and lactose. Thermophilic bacteria were more susceptible to the action of sugar than *Streptococcus lactis* and *Streptococcus liquefaciens*. Yeasts were more resistant than bacteria. Lactose had no preserving value with the yeasts studied. These authors also studied the effects of acids alone and in combination with these sugars.

The high moisture and sugar content of jellies, jams, and marmalades makes them quite susceptible to spoilage by yeasts and molds. Various factors influence the type and rapidity of such spoilage. Bitting⁴² used two yeasts and two molds in experimental packs to determine the effect of such variables as vacuum, temperature, acidity, and type of closure. Yeasts developed in a vacuum as high as 25 inches and were normal in appearance. *Oidium lactis* was not harmed by this vacuum but the *Aspergillus* species was inhibited. Bitting said that a temperature of 65.5°C. (150°F.) was sufficient to inhibit yeasts when the glasses were reversed for two minutes. However, with heavy yeast infection, heating to 71°C. (160°F.) was not sufficient for sterilization. Acidity to two per cent or more aided greatly in sterilization.

Drying of Fruits. Dried fruits are by no means devoid of microbial life. They do not undergo spoilage, however, as long as the moisture content is kept low. How low it must be depends on many factors. Prescott⁴³ found few dry foods to be sterile. Long storage, however, caused the number of microorganisms to become much lower. Mold spores were more prevalent than other organisms. Yeasts are commonly found in dried fruits. According to Clague⁴⁴ the microbial content of dried foods may vary from a few thousand per gram as a maximum on dried fruits up to several millions per gram on dried vegetables. Greater reductions in the bacterial load were noticed with fruits than with vegetables. The fruits examined by Clague were prunes, raisins, and apricots. These were used because they represented the dried fruits usually sold on the market. Numbers of organisms on the prunes were very low, 80 bacteria per gram being the highest count obtained. Molds were present on all samples but yeasts were found on only one sample. A maximum number of bacteria on dried apricots was 850 per gram; yeasts were not encountered on any of the samples, and molds were demonstrated on only one sample. The low number of microorganisms on the apricots may be explained by the fact that they had been sulfured. More molds were found on raisins than on prunes or apricots. The steaming applied to raisins to make it possible to remove the seeds, probably accounts for the few microorganisms present.

44. Clague. 1936. *Food Research* 1, 45-59.

Dried fruits may, under proper conditions of moisture content and temperature, undergo several types of spoilage. Essu and Cruess⁴⁵ found yeasts to be the cause of "souring" of prunes and dates. The spoilage was controlled by heating in a sealed container so that all parts of the container and contents reached 60°C.(140°F.). Mrak and Baker⁴⁶ found a white sugar-like substance on dried fruit to be rich in yeasts. These fungi may cause deterioration. Many belong to the genus *Zygosaccharomyces*.

Pasteurization of Dried Fruits. On account of the fact that dried fruits harbor so many microorganisms, Fellers⁴⁷ carried out experiments to determine whether such fruits as figs, raisins, and prunes could be heated to pasteurization temperatures without injuring their texture or flavor. He observed a percentage reduction in the number of organisms from 93 to 99 per cent. In the case of dates, large commercial continuous pasteurizers are now in use. Several thousand cases of dates are processed daily. The laboratory experiment showed that temperatures of 71.1°C.(160°F.) to 85°C.(185°F.) at humidities of 70 to 100 for 30 to 90 minutes were effective on the different dried fruits.

A few inoculation experiments were also made. Dates, figs, raisins, and prunes were coated with cultures of *Escherichia coli* and subjected to various pasteurizing treatments. In all cases where the relative humidity was 75 per cent or more, a 30-minute exposure to 71.1°C.(160°F.) was sufficient to destroy all the organisms. Approximately 40 such tests were made. Using *Eberthella typhosa* on dates, a single experiment showed complete destruction of the organisms after exposure to 76.7°C.(170°F.) for 25 minutes, or 71.1°C.(160°F.) for 30 minutes, at a high (unmeasured) humidity. Since the *Escherichia coli* is considered more resistant than the *Eberthella typhosa*, such findings are significant.

Fellers also carried out a few experiments to study the effect of storage on dried fruits heavily inoculated with *Escherichia coli*. *Escherichia coli* died out in 15 days on prunes and in 30 days on raisins, dates, and figs. To eliminate pathogenic microorganisms which might be introduced during packing and to destroy spoilage microorganisms Clague and Fellers⁴⁸ attempted to use heated humidified air for pasteurizing fruits. Using *Escherichia coli* as index of pasteurization efficiency, the following effective minute processes were obtained: 87°C.(188.6°F.) for 20 minutes at 96 per cent relative humidity or above; 82°C.(179.6°F.) for 30 minutes at 75 per cent relative humidity; 71°C.(159.8°F.) for 50 minutes at 90 per cent relative humidity; 66°C.(150.8°F.) for 60 minutes at 100 per cent relative humidity; and at 63°C.(145.4°F.) no effective pasteurization time under 80 minutes. Sporeforming bacteria and molds constituted a considerable part of the microbial flora on raw dried dates. While pasteurization did not always reduce the number of bacteria, it did destroy larvae and eggs of insects. Strains of *Escherichia coli* were found to be more

resistant than related pathogenic forms. Pasteurization destroyed virulent *Mycobacterium tuberculosis* swabbed on the dates.

Clague's "Method for Bacteriological Examination of Dried Foods." Two methods were used. The first was to take whole pieces of fruit and aseptically cut off portions until a 10-gram sample had been obtained. A tared, sterile petri-dish cover was placed on a balance and the sample cut into it until 10 grams had been obtained. This sample was then transferred to 90 ml. of sterile water.

The second procedure was to place five whole prunes or pieces of other fruits in 100 ml. of water. After shaking the bottle well by hand, one ml. was plated directly, or diluted further; thus, one ml. was considered as representing 5/100, or 1/20, of the total number of microorganisms per piece of fruit. By weighing the fruit the count per gram as well as per piece may be secured by this method.

The procedure with powdered fruits was to weigh 10 grams directly into a sterile wide-mouth bottle.

Use of Sulfur Dioxide for Preserving Fruits. Sulfur dioxide has been used for a long time in dried fruits for preserving color, and for preserving other fruit products in some countries. Atkinson and Strachan⁴⁹ and Fisher, Mrak, and Long⁵⁰ have discussed some of the mechanical problems which are involved. Only its bacterial properties will be considered here. In solution it has an appreciable toxic effect on microorganisms, as shown by a number of reports. Fernbacher⁵¹ reported that several species of yeasts were affected by sulfur dioxide. Fermentation by Froberg yeast was stopped by 7.5 mg. of sulfur dioxide in 100 ml. of medium, while with Saaz and Logos types 6.8 and 9.2 mg., respectively, were required. According to Hailer,⁵² yeasts are more sensitive to sulfur dioxide than are molds and bacteria. He stated that the concentrations required to kill are for molds 1/150, for yeasts 1/186, and for bacteria 1/520 gram molecules per liter. According to Cruess,⁵³ yeasts differ in their reaction to sulfur dioxide. Wild yeasts and molds were inhibited, while the true wine yeasts were not. Such data indicate the futility of making general statements about the effect of bactericidal agents on microorganisms. One paper by Moreau and Vinet⁵⁴ may be mentioned because in it was pointed out the fact that it is free sulfur dioxide which acts on microorganisms. Moreau and Vinet pointed out that sufficient fresh sulfur dioxide must be added to permit a residual uncombined amount to be available for action as an antiseptic.

A new use of sulfur dioxide has developed during recent years in the shipping of fresh grapes. Winkler and Jacob⁵⁵ have discussed the subject. The purpose of using sulfur dioxide in this manner is to delay deterioration caused by development of molds and other spoilage-producing microorganisms. Jacob reported that in 1928, 15,000 carloads of grapes were treated. He stated that a concentration of 50 parts of sulfur dioxide per million parts of grapes (.005 per cent) will delay the development of molds and other microorganisms, so that the rate of deterioration is about one-half

that of similar untreated grapes, stored under similar conditions. Most of the grapes were treated after they had been loaded in refrigerator cars. Sulfured fruits may contain objectionable amounts of hydrogen sulfide if yeast fermentation occurs. Sage⁵⁷ recommended pasteurization if active yeasts are present.

Preservation of Fruits by High Pressures. Some food preservation methods affect the flavor. Consequently, experiments were carried out to determine the effect of high pressures on the bacteria in fruit and other food products. Could they be destroyed in this manner, the flavor of the product would probably not be affected or altered. Not many experiments have been carried out with food products. Consequently, it is probably not amiss to review the results of a few experiments with pure cultures.

Regnard⁵⁸ stated that yeasts could stand a pressure of 1,000 atmospheres for one hour without being destroyed. Melsens⁵⁹ used pressures of 8,000 atmospheres and noticed no diminution in the vitality. This early work has been checked by some work in America which seems to have been carried out to determine whether foods could be preserved by pressure. Hite, Giddings, and Weakley⁶⁰ studied the effect of pressure on bacteria in canned fruits and vegetables. The bacteria which caused spoilage of sweet, ripe fruits could be destroyed by pressure. One hundred thousand pounds for 10 minutes stopped the fermentation of grape juice. Apple juice which was subjected to 60,000 to 80,000 pounds for 30 minutes remained sweet. These authors kept apple juice which had been subjected to 90,000 to 120,000 pounds for five years. Inconsistent results, however, were secured with blackberries and raspberries. Tomatoes also gave such results. The work indicated that more study is necessary to overcome some of the difficulties of the process in its application to food preservation. Bridgman⁶¹ reported that egg white became somewhat stiffened when it was exposed to 75,000 pounds per square inch for 30 minutes at 20°C. (68°F.). This conclusion may have significance in attempts to explain how bacteria are killed by pressure. Larson, Hartzell, and Diehl⁶² found that direct pressure of 6,000 atmospheres would kill nonsporeforming bacteria when applied for 14 hours. It required 12,000 atmospheres for the same length of time to kill the sporeformers. This has much significance in the sterilization of foods by this method, since the sporeformers cause much of the trouble in spoilage. In an atmosphere of carbon dioxide, 50 atmospheres for 1.5 hours killed nonsporeformers. High pressures have not been used for food preservation on account of the uncertainty of results and the mechanical difficulties of applying them.

FROZEN FRUITS

As is the case with other frozen foods, the types and numbers of microorganisms on frozen fruits is determined largely by those in the raw

products and the methods of freezing and storage. In general, yeasts and molds make up a larger part of the flora of frozen fruits than of frozen vegetables. This fact determines to a considerable extent the type of spoilage which may occur in the defrosted fruit. The bacterial flora may be quite heterogeneous. Tanner and Wallace⁶³ studied certain phases of methods of preservation using temperatures of $-16^{\circ}\text{C}.$ ($3.2^{\circ}\text{F}.$), $-40^{\circ}\text{C}.$ ($-40^{\circ}\text{F}.$), and $-79^{\circ}\text{C}.$ ($-110.2^{\circ}\text{F}.$). In general, the degree of cold had little effect on the death rate of bacteria.

A few experiments with *Clostridium botulinum* in several vegetables and a few fruits showed that spores of this organism survived freezing at $-16^{\circ}\text{C}.$ ($3.2^{\circ}\text{F}.$) for 14 months. The toxin also showed no decrease in strength when stored at $-79^{\circ}\text{C}.$ ($-110.2^{\circ}\text{F}.$) for the same time. Vegetables to which detoxified spores were added before freezing at $-14^{\circ}\text{C}.$ ($6.8^{\circ}\text{F}.$) for 14 months, became toxic in three to six days when allowed to thaw and stand at room temperature. Toxin formation was observed in a few instances in inoculated, thawed, frozen fruits despite a hydrogen-ion concentration which has been found to be protective in canned fruits. Formation of toxin under these conditions was probably made possible by the development of other microorganisms which created conditions favorable for *Clostridium botulinum*. A similar situation in home-canned Bartlett pears was reported by Meyer and Gunnison.⁶⁴

Frozen fruits are not sterilized; they must, therefore, be prepared under conditions which prevent entrance of *Eberthella typhosa*, *Salmonella* organisms, etc. Special attention must be given to the water supply. Tanner and Wallace⁶³ inoculated the clear juice and juice and cherries with the organisms just mentioned. When the organisms were frozen in the clear juice, no viable cells could be found after two weeks at $-14^{\circ}\text{C}.$ ($6.8^{\circ}\text{F}.$). However, when held at $-16^{\circ}\text{C}.$ ($3.2^{\circ}\text{F}.$) in the presence of both cherries and juice, they remained alive for five months. Such results emphasize the need of establishing the purity of a water supply used in preparing frozen fruits. The danger rests in considering them in the same category as canned fruits. Cruess and Overholser,⁶⁵ Woodruff,⁶⁶ and many others have discussed other aspects of the subject.

Some of the small fruits which are preserved by freezing, such as strawberries and cherries, are handled mainly by hand and are thus subject to contamination. In order to ascertain the survival period of pathogenic bacteria, McCleskey and Christopher¹⁹ heavily inoculated sliced strawberries with about five million cells per gram and held them at $-18^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$). The following survival periods were observed:

<i>Eberthella typhosa</i>	6 months
<i>Staphylococcus aureus</i>	5 months
<i>Salmonella aertrycke</i>	1 month
<i>Salmonella schottmülleri</i>	1 month
<i>Salmonella paratyphi</i>	Not recovered

63. Tanner and Wallace. 1931. Soc. Expt. Biol. and Med. Proc. 29, 32-34.

65. Cruess and Overholser. 1925. Canning Age.

66. Woodruff. 1930. Ga. Agr. Expt. Sta. Bull. 163.

Using unsliced but sweetened strawberries, *Eberthella typhosa* was still present in small numbers after 14 months' storage at $-18^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$).

Fruits are in the same category as are vegetables with respect to decrease in microbial numbers during storage. The number of viable organisms decreases markedly but not to the point of complete sterility. Smart⁶⁷ reported viable bacteria, yeasts, and molds in sealed tins of frozen strawberries which had been stored at $-9.4^{\circ}\text{C}.$ ($15^{\circ}\text{F}.$) for three years. Lochhead and Jones⁶⁸ studied the problem with strawberries and raspberries. They were packed in paraffin-lined, one-pint cartons. The strawberries were packed in a sugar sirup of 55° and the raspberries in a sirup of 45° Balling. After packing, the fruits were stored at $-17.8^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$) and kept frozen until examined. Samples were removed for examination over 37 weeks. Great variations were noted in freshly packed materials, as have been reported by others. Such variations are explainable, for the raw materials may be of varying age and carry different amounts of soil. The variations which Lochhead noticed became largely obliterated during storage. Pronounced differences in microbial content owing to methods of packing were not observed. Frozen fruits were found to harbor a considerable number of yeasts and molds. Members of the coliform group were few in number as was also the case with anaerobic sporeformers. Smart⁶⁹ observed that less than two per cent of the microorganisms found on fresh blueberries survived storage of seven months at $-9.4^{\circ}\text{C}.$ ($15^{\circ}\text{F}.$). While the types which are found in blueberries do not affect the healthfulness of the product, they are sufficient to cause spoilage in a few hours at room temperature. Prompt handling, freezing, and storage should give a frozen product offering no problems to the packer or consumer. A high number of bacteria probably indicates inefficient washing.

Berry's⁷⁰ observations on microorganisms in frozen berries showed that microorganisms died out more rapidly in the temperature zone between -9.4 to $-6.7^{\circ}\text{C}.$ (15 to $20^{\circ}\text{F}.$) than at $-20.5^{\circ}\text{C}.$ ($-5^{\circ}\text{F}.$). Growth of microorganisms was noticed in non-airtight containers at -3.8 to $-2.2^{\circ}\text{C}.$ (25 to $28^{\circ}\text{F}.$) in contrast with a rapid decrease in numbers in sealed containers. Berries in airtight containers at storage temperatures as high as $-3.8^{\circ}\text{C}.$ ($25^{\circ}\text{F}.$) did not spoil; strawberries, however, did not keep well at this temperature. The observation that microorganisms die out more rapidly at $-9.4^{\circ}\text{C}.$ ($15^{\circ}\text{F}.$) than at lower temperatures had been previously reported by Prescott, Bates, and Highlands.⁷¹ Berry⁷² suggested that this might be due to formation of lethal amounts of carbon dioxide from respiration of the berries when they are frozen more slowly. Results of experimental work did not confirm this.

Application of the Howard Microscope Method for Detecting Spoilage in Berry Products. Unless berries are handled promptly, they are susceptible to deterioration by molds. Several common species are involved. In view of results secured with the Howard method for detecting excessive mold growth in tomato products, Needham and Fellers⁷³ investigated its use on berry products. They soon found that these products should not be held more than one day under ordinary cannery conditions. High mold count in fresh or canned blackberries or strawberries indicates a high percentage of soft or moldy fruit. High yeast counts indicated spoiled and fermented fruit; and in general, high mold and high yeast counts occurred together. Highest mold counts were obtained when the pulp alone was sampled. Juice contained only very little mold. Counts obtained on the entire contents of the can (both pulp and juice) were somewhat lower than those on pulp alone, but should be determined preferably to those on pulp alone. Blackberry jelly contained little mold, yeasts, or spores regardless of the condition of the raw product. In strawberry and blackberry jams the mold count increased in proportion to the mold in the raw material, while the yeast count had a slight tendency to decrease. Preliminary experiments indicated that blackberries or strawberries containing 5 to 10 per cent of decayed or moldy berries by weight gave 40 per cent or more positive mold fields in the combined pulp and juice. Moderately high mold count may be obtained on soft, mushy, or overripe fruit showing no readily visible evidence of mold, especially with blackberries.

Before the Howard method may be used on a large scale on fruits, a standard technic must be developed.

Wildman's⁷⁴ Method for Examination of Canned Raspberries and Blackberries for Mold. This procedure was devised to detect the presence of primary spoilage in berries before they are packed.

(1) Examination is made on the basis of a No. 2 can. Where larger cans are to be examined, pour the contents into a large pan, and take a No. 2 can sample at random.

(2) Select a quart Mason jar with glass top and fill one-fourth full with water. Pour in sample, and water, and rinse several times with water until color has disappeared from juice. Avoid as much breakage of fruit as possible.

(3) Finally, cover berries with water, add 10 gm. of fresh anhydrous sodium sulfite and 10 ml. of concentrated hydrochloric acid. Allow to stand over night.

(4) Fill a white bottom pan about three-fourth inch deep with water. Pour about one-fourth of the berries into a 15-mesh sieve, allow to drain, and transfer to the white bottom pan.

(5) Examine berries for mold. Moldy berries are generally somewhat darker in color. Consider only as moldy those berries which have exterior mold filaments covering at least three drupelets. The presence of exterior mold can be detected with an ordinary hand lens by turning the suspicious berries over slowly in the water and examining the outline of the berry against the white pan. The work is less tedious by the use of a wide field binocular microscope, such as is used in the examination of butter, held over the pan by a suitable arm and support.

(6) Place moldy and passable berries in separate dishes and keep covered with water until examination is completed. Finish examination, using portions of about one-fourth of the sample. Drain moldy berries on sieve, transfer to tared watch glass, drain off excess liquid by turning watch glass on edge and holding berries with hand, and weigh. Weigh passable portion similarly and compute percentage.

In 'Tentative U. S. Standards for Grades of Fruit Preserves (or Jams)'^{74a} tolerances have been proposed for various fruit preserves. Fruit preserves or jams that consist of a single variety of fruit may contain mold filaments not exceeding the maximum percentage of positive fields shown in the following table. When they consist of a combination of fruits they may contain mold filaments not exceeding the maximum percentage of positive fields for the predominating variety:

Spoilage of Processed Fruits by *Byssochlamys fulva*. This mold has become a problem in processed fruits in England and the United States. It is a very resistant species, according to Olliver and Smith,⁷⁵ readily cultivated on various media. Tissues of processed fruit are readily disintegrated even under reduced oxygen pressure. Olliver and Rendle⁷⁶ found it on fruit in the fields and believed it to be present in soil. Its ascospores resisted 86 to 88°C. (186.8 to 190.4°F.) for 30 minutes in many fruit sirups. Further information on heat resistance of *Byssochlamys fulva* has been given by Gillespy,⁷⁷ who found the maximum heat resistance of the ascospores to be at about pH 5; resistance at pH 3 was considerably greater than at pH 7. The protective effect of sucrose in solution was greater at 90°C. than at 85°C. Survival time for 10 per cent of the ascospores, when heated in fruit sirups, exceeded 45 minutes at 90°C. (194°F.). Enzyme activity continued in stored bottles even long after the fungus had died out.

An unusually heat-resistant mold which grew in a high vacuum has been reported by Williams, Cameron, and Williams.⁷⁸ The species was isolated from canned blueberries where it grew on the surface as in the form of small plaques. Growth apparently did not occur below the surface.

At 82°C.(180°F.) 9.7 minutes were required to destroy conidia, while the sclerotia required 1,000 minutes. The logarithmic order of death did not seem to hold. The mold was able to develop in high vacuum above 25 inches.

✓ **Spoilage of Canned Pineapple.** Losses from spoilage of canned pineapple have been small. Occasional outbreaks have made it possible to determine the causal organisms. Spiegelberg,⁷⁹ in several publications, has summarized the literature and made significant contributions. The pH of canned pineapple ranges from 3.5 to 4.7, depending on the pH of the raw fruit. Examination of sound cans showed that many contained viable microorganisms consisting of two types of sporeformers which survived the process but which were unable to develop in the cans. Oxygen and pH were said to be the chief factors which limited growth of these organisms. One organism grew with scum formation on culture media while the other did not. The butyric organism produced spores and thus showed some resistance to heat. Processes used in commercial practice were said to be generally satisfactory. With a pH of 4.4 to 4.5 and below, the standard of 87.8°C.(190°F.) in the fruit after the cooking process was adequate to insure sterility, but with a pH of 4.5 and above a temperature of 93.3°C. (200°F.) or above was required to eliminate arrested swells. Even with these temperatures butyric acid-forming organisms persisted. When the pH was 4.4 butyric spoilage was entirely absent even with substandard cooks; low pH and lower cooks permitted other types of spoilage to appear.

FRUIT JUICES

The increased use of unfermented fruit juices in America has necessitated constant study of the various methods of preservation. Application of heat, or pasteurization, has been the most satisfactory method of preservation even though the flavor is always altered. In order to minimize the change in flavor, as low a temperature as possible is used. Other methods of preservation are constantly proposed. Some of these newer methods have involved attempts to extract sterile juice from the fruits or impregnation of the juice with some such gas as carbon dioxide.

The technology of fruit juices and related products has been comprehensively treated by Charley and Harrison.⁸⁰ Special attention was given to pasteurization preservation. A Committee of the American Public Health Association⁸¹ recommended that some control should be applied to this industry. They believed that a need existed for quality standards.

Grape Juice. This is the unfermented juice of the grape. It enjoys wide sale in the United States. The best grapes are used in its manufacture and in this respect grape juice may differ from apple juice. In the preparation of apple juice, frequently the cull apples or windfalls are used. Grapes are usually as clean as apples, since they grow on vines above the ground and are harvested before they are too ripe to handle. Therefore,

79. Spiegelberg. 1934. Pineapple Quarterly for 1934 and 1935.

80. Charley and Harrison. 1939. Tech. Commun. No. 11, Imp. Bur. Hort. and Plantation Crops, Kent, England, 104 pp.

81. Amer. Pub. Health Assoc. Yearbook, 1940-1941, 101-105.

they probably carry fewer bacteria than do apples. Cruess⁸² and others have described the manufacture of grape juice.

Grapes are washed and crushed, which consists of breaking the skin but not pressing the fruit flat. After being stemmed, they are cooked in aluminum kettles at 63°C.(145°F.) with constant stirring. They are then pressed under a pressure of about 170 tons. The juice is heated to 72°C.(160°F.), and skimmed. It is then run into glass-lined carboys and allowed to stand in tiers for several months, during which time the argol settles out. The juice is then filtered off and is ready for bottling. Sugar is added to the extent of one pound for every five gallons of juice. The bottles are pasteurized at 77°C.(170°F.) for 30 minutes. The temperatures of pasteurization suggested by Bioletti⁸³ were considerably higher for bottles. Cruess and Hintze⁸⁴ recommended lower temperatures of pasteurization than those mentioned.

Pederson and Tressler⁸⁵ have published results of many experiments on preparation and pasteurization of grape juice. Pederson⁸⁶ stated that relatively few organisms, primarily molds and bacteria, survive the heating of Concord grapes for extraction. A large number of organisms are introduced in the pressing operations. These apparently are not the result of growth in the juice but are due to contamination from equipment. These organisms, which are mainly yeasts, are apparently more resistant to heat than the yeasts natural to the grape. All organisms are killed in the pasteurization before filling carboys. The juice in carboys is occasionally spoiled by mold growth. The source of this contamination may be mold spores on the corks used for closure or mold spores on corks which had been pushed into the carboys when previously used. The latter source of contamination can be overcome only by removal of these corks. The former may be overcome by dipping the corks in hot paraffin immediately before use. Pederson stated that lower temperatures could be used. A temperature of 71.1°C.(160°F.) is apparently sufficient, although 73.9 to 76.7°C.(165 to 170°F.) would be safer, especially for carboy juice made from Concord grapes. The majority of yeasts and bacteria are killed at temperatures well below 62.8°C.(145°F.). The molds are more resistant but are apparently unable to withstand temperatures much above 68.3°C.(155°F.).

Grape juice has been cleared of its objectionable turbidity by means of enzymes, by Willaman and Kertesz.⁸⁵ Molds grown on appropriate media produce an enzyme which converts most of the pectin of grape juice into other soluble substances. A portion of the pectin comes down as a flocculent precipitate which occludes other suspended matter. By simple filtration this precipitate is removed, leaving a brilliantly clear juice. Production of the enzyme from *Penicillium glaucum* and practical use of the process is described in detail.

Apple Juice. In America this is the fresh, unfermented juice of the apple. It is sometimes called apple cider, sweet cider, or cider and is to be distinguished from the English product which has undergone fermentation. The apples from which the juice is expressed are frequently those which cannot be sold as eating or cooking apples. The use of such apples is probably not objectionable if they are sound and clean. When old, partly-spoiled apples are used, a low-grade juice is secured. Today more attention is paid to the condition of the raw materials. The apples are washed and thereby much foreign matter is removed. Truelle⁸⁶ stated that if cider apples are washed and the water filtered, an ill-smelling filtrate is secured. He believed that this residue would have given a bad taste to the cider. He recommended that baskets of apples, about to be pressed, be placed in a stream of water for a while, and then allowed to dry—a practice commonly followed in Germany, Austria, and Switzerland. The subject was also studied by Müller-Thurgau and Osterwalder,⁸⁷ Vaton,⁸⁸ and Alliot and Gimel.⁸⁹ Alliot and Gimel studied the effect of several disinfectants in the wash water and reported that calcium hypochlorite, in a strength of 40 to 60 grams per hectoliter, gave best results. Sufficient bacteria were destroyed to leave a clearer field for *Saccharomyces mali*. Apple juice prepared in this manner was a better product. Perrier⁹⁰ soaked apples in water containing .5 per cent of formaldehyde for 15 to 24 hours. After washing in fresh water, the apples were pressed with apparatus which had been washed with formaldehyde water. Samples of juice from apples treated in this manner resisted fermentation for a considerable time. When pitched with yeast, such juice fermented normally.

It is quite probable that more attention could be paid in America to cleaning apples than is now given them. Disinfectants have not been used to any extent, if at all. The present procedures, founded as they are on a rule-of-thumb basis, could well derive benefit from the results of bacteriological and chemical researches.

Use of too-high temperatures of pasteurization causes marked changes in flavor of apple juice. Cruess and Aref⁹¹ studied the possibility of using lower temperatures than ordinarily used. Since molds cannot develop in canned juice even though they may not be killed by the heat, because of absence of oxygen owing to its combination with metals in tin plate, all that needs to be done is to kill the yeasts. Cruess and Aref's results showed that it was practicable to pasteurize at as low a temperature as 56.1°C.(133°F.). In large scale experiments 57.2°C.(135°F.) and 60°C.(140°F.) kept juice in No. 1 tall cans perfectly. When pasteurized at the latter temperature, the flavor was quite like that of fresh, unheated juice.

Possibility of Communicable Disease Dissemination by Apple Juice. Before apples are washed, the purity of the water should be established. So

far as the author can determine, experiments have not been carried out, in America, to determine the behavior of *Eberthella typhosa*, for instance, in fresh apple juice. A few investigations have been reported in Europe.

Bodin⁹² reported that this organism was destroyed in two to 18 hours. Paque,⁹³ however, reported 24 cases of typhoid fever caused by sweet cider. The apples were washed in polluted water. A similar epidemic, it was stated, had been caused a few years before. Discussions by several hygienists indicated possible dissemination of typhoid fever by beer with low alcoholic content. Paque then carried out experiments to determine how long the members of the typhoid group could live in cider. *Eberthella typhosa* and *Salmonella paratyphi* were destroyed in a week. *Salmonella schottmülleri* was more resistant. It was able to live a week. Paque believed that cider 15 days' old would be safe. He stressed the necessity of using clean water for washing the apples.

Spoilage in canned fruit juices and in other similar products may be reduced by attention to several steps in the canning operation. Microorganisms may be eliminated by using sterile cans. Bitting⁴² found this to be the case with jams and marmalades. Her conclusions might hold for canned fruit juices which are often packed without heat processing after the cans have been filled with hot juice and closed. Pearce⁹⁴ pointed out the value in this connection of inverting the can in order to sterilize its entire interior. When this method is relied on, the juice must not be allowed to cool between closure and inversion.

Clarification (Filtration) of Apple Juice. Desire for a clear product has caused large commercial pressers of apples to clarify the juice by one method or another. Filtration through various materials was the first method used. This procedure may also be looked upon as a method of preservation, since a great many bacteria and yeast cells are thus removed. One of the present methods is to mix from one-half to two per cent of "filter cel" with the cider. This is then passed through a filter press. In large quantities of apple juice, about 300 pounds of "filter cel" are used per 5,000 gallons of juice. After filtration the apple juice may be bottled or stored in glass-lined or wooden tanks. Grove⁹⁵ reported a study of the use of various possible substitutes for filtration. None of the various attempts were successful. Grove stated that filtration was the best method for removing yeast and bacterial cells from cider, as did Carpenter and Walsh.⁹⁶ The Dominion Bacteriologist of Canada⁹⁷ tested the efficiency of the Seitz filter for removal of organisms before bottling. Experiments were made at pressures of 10 and 24 pounds per square inch. Sterile filtrates were found to be possible at pump pressures up to 24 pounds. This pressure was greater than that considered possible by Carpenter, Pederson, and Walsh who regarded 10 pounds per square inch as the

maximum safe pressure. Even when the filter was in use for five hours, there was no evidence that microorganisms grew through the filter.

Pasteurization of Apple Juice. Application of heat to destroy microorganisms seems to be the safest method for preserving apple juice, even though the taste may be altered. Freezing is possible under certain conditions but this method is not convenient at all times. Spoilage of apple juice may be due to fermentations caused by yeasts or other changes caused by bacteria. Infection of the juice is easily explained. Diehm⁹⁸ stated that minimum heat treatment to destroy mesophilic bacteria is 15 minutes' heating at 70°C.(158°F.), 10 minutes at 80°C.(176°F.), and five minutes at 90°C.(194°F.). Gore⁹⁹ was able to preserve fresh apple juice satisfactorily by pasteurization. The juice was heated to 65 to 70°C.(149 to 158°F.), and kept for six months without fermentation. He stated that it could also be sterilized in tin containers, although 65°C. for 30 minutes was not quite sufficient for all varieties which were tested. Tin containers are not to be recommended, however, for this product. Apple juice today is heated under vacuum to remove air and then pasteurized. The best treatment for cider in glass containers consisted of heating for one hour at 65°C. or one-half hour at 70°C. Cruess and Irish¹⁰⁰ reported that apple juice could be sterilized by a temperature of 65.5°C.(150°F.) for 30 minutes. Carbonated juice was said to require 76.7°C.(170°F.) for 30 minutes. Wiegand¹⁰¹ advised great care in preheating apple juice before bottling if marked alterations in taste were to be avoided. Preheated juice was filled directly into sterilized cans within one-quarter of an inch of the top. The cans were heated in an exhaust box at a temperature of not over 71.1°C.(160°F.) to drive out surplus air. Exhausting of No. 2½ tins for not less than five minutes was advised and from six to eight minutes for No. 10 tins. Processing in open-bath cookers at 71.1°C. for 20 minutes for No. 2½ cans and for 30 minutes for No. 10 cans, was advised. Prompt cooling to 32.2°C.(90°F.) was also recommended.

Bottling of fermented apple juice is carried out in England as described by Grove.¹⁰² Some of his conclusions could be applied in America to preparation of fresh juice. He advised that iron containers be avoided, if possible, since too much iron might cause darkening of the product. Juice from tart apples was successfully flash-pasteurized and canned at 71.1°C.(160°F.) or higher although a cooked flavor might be imparted (Pederson and Tressler.¹⁰³

Preservation of Fresh Apple Juice With Chemical Reagents. Prohibition of the sale of fermented beverages in the United States stimulated investigations on the preservation of fruit juices by other means than low temperatures. Several investigators turned to the chemical compounds

which had been suggested for other foods. Gore¹⁰⁴ reported that sodium benzoate in quantities of .03 to .15 per cent checked alcoholic fermentation but that acetic acid fermentation developed with an alteration in flavor. The latter statement would indicate that the alcoholic fermentation had progressed appreciably. Scott and Will¹⁰⁵ reported that, for commercial purposes, .2 per cent of sodium benzoate was required for efficient preservation, although this amount would not prevent the acetic acid fermentation. Apparently *Acetobacter* are not very susceptible to the action of sodium benzoate. According to Rice and Markley¹⁰⁶ and Tanner and Strauch,¹⁰⁷ fermenting yeasts are not especially susceptible to sodium benzoate; this finding was later confirmed also by Diehm.⁹⁸ Rice and Markley found that sodium benzoate would not do much good if there were many yeasts present, or if the juice was not kept cool. With warm juice as much as .5 per cent of sodium benzoate was necessary. Similar conclusions were reached by Tanner and Strauch, who worked with a number of pure yeast cultures. They observed marked differences among yeasts in resistance to sodium benzoate. They showed, furthermore, that fresh apple juice to which .1 per cent of benzoate had been added by law, would ferment. Cruess and Richert¹⁰⁸ reported that hydrogen-ion concentration greatly influenced action of sodium benzoate on microorganisms.

They observed a much stronger action at pH values of 2.5 to 4.5 than at 5 to 9. The concentrations of benzoate required to prevent the growth of *S. ellipsoideus*, *S. cerevisiae*, a mucor mold, two penicillium molds, three strains of mycoderma yeast, a lactic acid bacterium, a vinegar bacterium, *E. coli*, *B. subtilis*, and *Cl. sporogenes* were greatly affected by the pH of the medium. Much more sodium benzoate was required at pH values near neutrality, e.g., pH 5 to 8 than at those in the acid range, 2.5 to 4.5.

Preservation of Apple Juice by Cold Storage and Freezing. Freezing has been considered to be a possible method for preserving apple juice for several decades. Gore¹⁰⁹ was one of the first to study the matter seriously. He found that when freshly expressed juice was chilled immediately to 0°C. (32°F.) it remained without noticeable fermentation for an average of 50 days. Gore stated that the juices suffered no deterioration but, on the other hand, became more palatable. Descours-Descares¹¹⁰ studied two methods of freezing. One involved a slow but uniform lowering of the temperature to —3 or —4°C. (26.6 or 24.8°F.) in 24 hours. The ice is drained off just below zero. The other method involved freezing at —6 or —7°C. (21.2 or 19.4°F.) with slow motion. This latter method gave very fine crystals which were drained and washed just below freezing. Development of freezing apparatus should greatly stimulate interest in this method of preservation. The microbiological features of the method are probably no different from those which are reported above in the discussion of freezing of fruits. Microorganisms tend to disappear rapidly in frozen

apple juice. In experiments by Berry and Diehl,¹¹¹ in which apple juice containing 2,000,000 microorganisms per ml. was used and it was stored at -5 , -9.4 , and 6.7°C . (23 , 15 , and 20°F .), over 90 per cent of the bacteria were destroyed in one month. At -2.2° (28°F .) many of the samples showed alcoholic fermentation in one month. The microbial content was lowered still further by prolonged storage.

Ropy Apple Juice (Sweet Cider). Slime or rope producing bacteria are responsible for losses in various foods. They are probably harmless, but so change the consistency of the foods that they are no longer desired. These organisms are, in general, unable to grow in the presence of acid. Consequently, acids are often added to foods to prevent their development. They cause this same change in apple juice before it becomes too acid for their development. They may also develop in some cider which is undergoing alcoholic fermentation. Grove¹¹² carried out some inoculation experiments with organisms which were known to cause rope. About a year elapsed before rope developed. A sediment appeared at the bottom of the bottle, most of which consisted of the rope-producing organisms. Kayser¹¹³ isolated four different microorganisms from ropy cider. Their characteristics were somewhat divergent and need not be reproduced here. The significant statement was made by Kayser that ropiness might be due to other factors than the mere presence of bacteria.

Off-flavored apple-juice caused by development of a special microorganism has been reported by Warcollier and Tavernier.¹¹⁴ The unnamed bacterium imparted a raspberry-like flavor.

Orange Juice. Much effort is being expended on methods of preparation and preservation of orange juice. The nature of the juice suggests that it is just as susceptible as the juices of all other fruits to the attacks of bacteria and yeasts. It is rich in organic acids, mineral salts, and carbohydrates, all of which, with the high amount of water, make a good medium for the development of microorganisms. The use of heat is ruled out by the alterations in flavor which it causes. Despite this a palatable orange juice is being packed and has been widely accepted. Townsend and Esty¹¹⁵ stated that two minutes at 76.7°C . (170°F .) were adequate for commercial sterility of California orange juice with a pH of about 3.7, sterilized prior to canning; to destroy contamination from cans and lids, a short treatment after sealing is necessary. For juice filled at 170°F ., two minutes at this temperature subsequent to closing should be satisfactory on sealed cans. If the filling temperature is below 170°F ., two minutes at 79.4°C . (175°F .) should be used.

Orange juice has been preserved by freezing. This method of preservation brings about minimum change in flavor. Juice from sound oranges is a sterile product, and effort is made to keep the bacterial content as low as possible. Enzymes act to bring about deterioration and every effort is

made to remove oxygen. The juice is frozen to a slush and finally hardened in an air blast at $-23.3^{\circ}\text{C}.$ ($-10^{\circ}\text{F}.$). Few, if any, data have been reported on the effect of such treatment on microorganisms that might be present. By analogy, we might expect a decrease in the number of viable microorganisms but not a condition of absolute sterility. Thawed, frozen orange juice is a perishable product.

Grapefruit Juice. This juice is now being put up in bottles and tin cans as are other fruit juices. The juice is pressed from the grapefruit in a manner similar to apple juice. According to Chace,¹¹⁶ the fruit is cut into halves or quarters depending on the size of the press used. After pressing, the juice should be strained and pasteurized immediately at a temperature of 75 to $80^{\circ}\text{C}.$ (167 to $176^{\circ}\text{F}.$). This seems to be a very important step in the preparation of grapefruit juice since quality of the product may be greatly harmed. The best method is to heat a thin film of the juice while it is in motion in a coil heated to the desired temperature. The juice should be conducted into carboys which are filled, leaving only sufficient room for the sterile cork. These carboys are then stored in a cool room for one or two months at not above $10^{\circ}\text{C}.$ ($50^{\circ}\text{F}.$) in order that sedimentation may take place. The clear supernatant liquid is decanted for bottling. Often the juices should be sweetened before bottling if the content of acid is above one per cent. Before bottling the juice is pasteurized again and run into the bottles which are capped and allowed to cool.

Freezing of Fruit Juices. This has been found to be a suitable method for preserving fruit juices without changing the flavor to any extent. Freezing has also been used to concentrate fruit juices; the ice is removed by filtration. Juices and sirups containing about 50 per cent of sugar have retained their flavors well in the frozen condition. The problems involved are more technical than microbiological. Most of the results of investigations on freezing fruits are applicable to fruit juices, although it is probably easier to destroy bacteria in the juice than in the fruit. McFarlane¹¹⁷ observed greater destruction of microorganisms in unsweetened juice than in juice-sucrose media stored at $-17.8^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$). Survival in juice-sucrose media varied with sucrose concentration. In some cases 50 and 60 per cent of sucrose did not protect. It is evident from McFarlane's discussion that preservation of fruit juices by freezing involves many factors.

Sterilizing Values of Fruit Juices. Owing to acids and other constituents, fruit juices are inimical to many bacteria. Most attention has been given to pathogenic bacteria. Douglas¹¹⁸ was inclined to attribute the lethal effect of fruit juices to their acid contents. He stated that two teaspoonfuls of lemon juice would kill two billion cells of *Eberthella typhosa* in less than 10 minutes. He pointed out that such acidity is quickly neutralized in the body. From investigations with 16 fruit juices and 19 condiments Sogo¹¹⁹ found "Yuzu" juice to possess the strongest sterilizing

power among such fruit juices as lemon, mandarin, orange, and strawberry juices. Juices of Japanese medlar, peach, pear, and sweet cherry had weak sterilizing powers. He attributed the sterilizing power of fruit juices to the fatty acid content. According to Lasseur and Renaux¹²⁰ agglutination of *Bacillus pyocyaneus pyocyanogenes*, *B. chlororaphis*, *B. prodigiosus*, *B. balticus*, and *B. subtilis* (Neisser, Marburg, and Michigan strains) by lemon juice is due to acidity, not to a precipitin. As pH approaches 6, by dilution or by neutralization of the juice, agglutinating power disappears. Heating or filtration of juice does not affect agglutinating power. Lemon juice does not agglutinate *B. mesentericus niger*, *B. megatherium*, or *B. caryocyaneus*. Curves are given for precipitation of *B. chlororaphis* and *B. prodigiosus* by lemon juice, citric acid, citric acid plus Na citrate and HCl, at pH .5 to 6.

Fresh juices of grapes with pH values of 2.6 to 3.2 also showed definite bactericidal properties against *Eberthella typhosa*, according to Rochaix and Jacqueson.¹²¹ *Escherichia coli*, *Salmonella paratyphi A* and *B*, Shiga dysentery bacillus, and *Vibrio cholerae* were killed in grape juice at periods varying from 15 minutes to three hours. The Shiga bacillus was more resistant than other organisms to the action of grape juice. The agent responsible for the destruction of bacteria is not mentioned, although the several constituents of grape juice are discussed.

Experiments by Beard¹²² showed an appreciable inhibition of the bactericidal effect of acidity at low temperatures. In orange juice the survival period varied from 50 hours for staphylococci to 170 hours for strains of *E. typhosa* and *S. dysenteriae*. This suggests the possibility of infection by this group of organisms in highly acid foods preserved only by storage at such temperatures. This possibility of infection is increased by the fact that such foods are frequently served with little storage—indeed freshness is often made a selling point. Danger is probably decreased by the fact that massive infection of the product would be relatively rare. It follows that preparation and handling of such foods should be subject to as rigid regulations and inspection as are applied to other types of food. The orange juice, after inoculation, was stored at $-4^{\circ}\text{C}.$ ($24.8^{\circ}\text{F}.$).

Dates. The saccharine nature of this fruit would suggest the possible presence of microorganisms. Dates are usually sold in small packages or in large boxes. Hunwicke and Grinling made a bacteriological study of dates, after having been prompted to do so by illness in a child who had partaken of dates. Eleven samples were examined, four of which were "block" or bulk dates, while the other seven were dates from smaller packages. The "block" dates were all free from intestinal bacteria, but coliform bacteria were isolated from all but one of the boxes. They were all of the *Escherichia coli* type. When dates are repacked in Europe, a solution of glucose is sprayed over them; this probably favors bacterial growth. These data tend to suggest that dates may be contaminated. Con-

vincing conclusions could only be reached, however, after more extended experiments. Fellers⁴⁷ reported the results of a large number of analyses of American dried fruits. None of the samples had undergone spoilage. Ten-gram samples of the fruits were placed in 90 ml. of distilled water in rubber-stoppered dilution bottles. Bacteria, yeasts, and molds were found to be present in considerable numbers. Eight of 79 samples contained lactose-fermenting bacteria. None was identified as *Escherichia coli*, although several closely resembled *Aerobacter aerogenes*. Fellers remarked that yeasts were conspicuous by their absence. This was probably due to the fact that plain agar was used; had agar with dextrose been used, yeasts would probably have developed.

Souring of Dried Dates. This deterioration is characterized by a soft dark-colored and matted together appearance and a peculiar aromatic odor and poor flavor. Fellers and Clague¹²⁴ found far more yeasts than bacteria to be present. Six types of sugar-tolerant yeasts were isolated which reproduced the spoilage when inoculated into sound dates. Although yeasts, mainly *Torulae* and *Willia* species were largely responsible for souring, *Acetobacter* were often present on secondary invaders. While souring was not produced when the moisture content was below 25 per cent, 23 per cent was suggested as a safe moisture maximum. Pasteurization, as discussed elsewhere in this book, effectively destroyed all date souring yeasts.

Souring of Figs. According to Caldis¹²⁵ souring is a term used to describe many different kinds of spoilage. He suggested that "fig fermentation" would be a better name were it not for the fact that the name souring has become so firmly entrenched. The first change consists of a change in color from pink to colorless. A pink liquid exudes through the eye. Gas bubbles appear throughout the pulp which becomes watery and loses its firmness. Fig souring is primarily an alcoholic fermentation. Later, acetic acid bacteria may oxidize the alcohol to acetic acid. Caldis isolated several strains of yeasts which were inoculated into normal figs. It was shown that insects disseminated the spoilage organisms.

The white substance generally considered to be sugar, which often covers dried prunes and figs during storage before processing and occasionally in cartons, was found by Baker and Mrak¹²⁶ to be a mixture of yeast cells and sugar crystals. The sporulating yeasts which were isolated were members of various genera. Especially interesting were the species which could develop in heavy concentrations of sugar. No obligate osmophilic yeasts were encountered. The cultural details will not be given in this book. Most of the species were reported by Mrak, Phaff, Vaughn, and Hansen¹²⁶ to be *Saccharomyces* or *Candida*.

CHAPTER 15

MICROBIOLOGY OF VEGETABLES AND VEGETABLE PRODUCTS

Vegetables and vegetable products are of interest to the bacteriologist on account of the possible relation of the bacteria which they carry to disease dissemination or decay. Considerable attention has been given to the relation of vegetables to disease dissemination. In America they are probably not very significant in this respect because fertilization of crops for human food with night soil and sewage is prohibited. It would be wrong, however, to state that vegetables could not carry harmful bacteria, because they are frequently handled under unsanitary conditions or inadequately washed.

Microorganisms on Fresh Vegetables. Since vegetables are grown in or near the ground, they may carry a heterogeneous flora of microorganisms. These organisms may be of interest on account of their ability to infect human beings or their relation to decay. Furthermore, the numbers of microorganisms are important if the vegetables are to be preserved. The greater the number, the greater will be the load on the preservation process.

Wurz and Bouges¹ showed that vegetables grown in infected soils or watered with infected water could transmit pathogenic bacteria. Kozyn² examined a number of samples of vegetables. Three had *Clostridium tetani* on their surfaces. Sixty samples showed no *Eberthella typhosa*, though the surface was more or less infected with intestinal bacteria. Generally speaking, bacteria were not found in the interior of the vegetables. *Escherichia coli* was found by Bessel³ on 59.6 per cent of fruits and vegetables, which were purchased on the open market. It was thought that contamination resulted from storing the vegetables where contamination was possible and from handling. Neumann⁴ reached the same conclusions, working with many of the common fruits and vegetables. Bacteria seem to stick so firmly to fruits and vegetables that even vigorous washing and rinsing do not remove them (Clauditz⁵). Microorganisms may persist for some time on fruits if the surface is unbroken. In some cases the juices may be germicidal.

Another phase of this question concerns the relation of vegetables from sewage farms to public health. Broad irrigation or sewage farming is used by several large cities for disposing of sewage wastes. Typhoid fever is said to increase every year from July to October in Paris. A goodly portion is attributed to vegetables raised on sewage land.⁶ While it was the original plan to use land fertilized in this manner for orchards and

pastures, the excellent yields caused some to be used for market gardening. An investigation of the crops raised on the sewage farms showed the following: peas, beans, potatoes, artichokes, leeks, cauliflower, carrots, turnips, sorrel, and spinach, all of which are usually eaten after cooking. There were also such vegetables as lettuce, dandelions, endive, onions, parsley, and radishes, which are most frequently eaten uncooked. It was stated that stringent laws were necessary to control the crops which should be raised on sewage farms (Marchoux⁷). This subject was investigated experimentally by Remlinger and Nouri.⁸ Their work indicated that the danger from this source was probably exaggerated. The results showed that none of the various pathogenic organisms used were taken up internally by the plants, and that the only possible source of danger was from organisms adhering to their surface. It was found that the only organisms which were retained by plants grown under conditions similar to those on well-managed, sewage-irrigation farms were *Bacillus anthracis* and *Clostridium tetani*, but, as the authors pointed out, the former organism is very rare in sewage water and the ingestion of *Clostridium tetani* is harmless. Water cress, however, was believed to have caused an epidemic of typhoid fever.

Kurk⁹ studied the microbiology of vegetables bought on the open market in Chicago. His attention was principally directed to finding members of the coli-typhoid group, streptococci, and anaerobic bacteria. He examined such foods as water cress, lettuce, celery, etc. *Escherichia coli* was found on 22 out of 29 samples, streptococci on three samples: 28 of the specimens contained bacteria which formed gas in lactose. Kurk could not correlate the condition of the store with his bacteriological results. The investigation was not an extensive one, but probably gives some idea of real conditions. The vegetables may be contaminated either by being grown in filthy soil or by careless handling after harvesting. In order to secure data with regard to the longevity of *Eberthella typhosa*, in the soil growing fruits and vegetables, Murillo¹⁰ incorporated the organisms in garden soil by spraying the low-growing fruits with a suspension. After 36 days, virulent organisms were still found. They lived 55 days in sterile sand. Such data indicate that salads and other dishes prepared from uncooked vegetables may spread disease. Experiments with *Vibrio comma* were equally conclusive up to three weeks. On the other hand, Rucker¹¹ did not find many *Escherichia coli* on fruits. Melick¹² found that the longevity of *Eberthella typhosa* in the soil depended on the source and the strain, the time varying from 29 to 58 days. Under natural conditions, radishes were infected after periods of 28, 35, and 37 days, and lettuce after 21 days. There was no evidence that the organisms entered the interior of the plant, but ordinary washing did not remove them. Creel¹³ studied the same

question, and reported that plants growing in soil carried on their leaves and stems organisms which existed in the soil. *Eberthella typhosa* was recovered from leaves which were apparently free from dirt. Under conditions which were most favorable to *Eberthella typhosa* infection lasted for 31 days, a period which is sufficiently long for lettuce and radishes to mature. Melick mentioned a number of instances where vegetables have caused disease. Wary¹⁴ reported an epidemic of typhoid fever in a London suburb, supposed to have been caused by eating water cress grown in beds fertilized by sewage. Pixley¹⁵ reported two cases of the same disease from eating uncooked rhubarb. Morse¹⁶ believed that 49 cases of typhoid in an insane asylum came from eating celery. The celery beds had received hospital sewage. Another outbreak occurred in Philadelphia where 18 out of 19 persons who ate water cress¹⁷ sandwiches became ill with typhoid fever. A visit to the farm yielded data which seemed to incriminate the cress. According to Mills, Bartlett, and Kessel,¹⁸ bacteria may be present on the surface of fruits and vegetables kept under moist conditions for 15 days or more. If the fruits and vegetables are covered to prevent a rapid evaporation of moisture, the survival period may be longer than 15 days. They carried out experiments to determine methods for elimination of pathogenic bacteria from these foods. Chlorination, for instance, was efficient for the pathogenic bacteria but did not affect cysts and ova. Alcohol was also ineffective for protozoan cysts and helminth ova. Neither was potassium permanganate an efficient disinfectant. These investigators reported that burning alcohol on the surface of vegetables or pouring boiling water over them did not destroy pathogenic bacteria. They found that after fruits and vegetables were dipped into boiling water for 10 seconds pathogenic bacteria, protozoan cysts, and ova were destroyed. This then seems to indicate that the simple procedure of boiling may be the satisfactory method for the treatment of these foods. This conclusion was confirmed by Ommyoji¹⁹ and Lu.²⁰ Exposure to boiling water for a few seconds destroyed *Eberthella typhosa* in cabbage, carrots, and a few other vegetables.

A more recent investigation of the subject was made by James²¹ with head lettuce. With fresh untrimmed lettuce the number of bacteria was much higher on the surface than in the interior of the head, but with increasing length of storage under ordinary room conditions, the bacterial count in the interior increased much more rapidly than on the outside. The bacterial count of lettuce stored at the temperature of 21°C. (69.8°F.), and under controlled humidity was much lower and the lettuce remained in good condition much longer. Lettuce heads which had been trimmed and washed in the market were much more highly con-

taminated throughout the head than unwashed lettuce, and similar results were obtained with washed lettuce stored at 20°C. (68°F.). The practice of washing lettuce before storing in the refrigerator was considered unwise as favoring more rapid bacterial growth.

The behavior of pathogenic bacteria in water and soil in nature has some bearing on the possible contamination of vegetables grown in infected soil or washed or freshened with infected water. Bitter secured some data on the behavior of *Escherichia coli*, *Eberthella typhosa*, and some of the paratyphoid bacilli in dry and moist soil. The above organisms lived for eight days in dry soil while in the moist soil they were present at the end of 60 days. A more recent contribution to our knowledge on this subject has come from Beard.²² Massive inocula of *Eberthella typhosa* were made into four types of soil placed in unglazed flower pots suspended over lysol trays and exposed out-of-doors to rain at any time and sun for about two-thirds of the day. Survival depended largely on moisture and was longest in the wet season and was much longer in adobe and adobe-peat-moss loam (six to seven weeks) than in sand (four to seven days). Without reviewing all of Beard's observations, it may be said that the type of soil and other conditions largely determine the results which are secured.

Other work has been done by Pfuhl,²³ Graucher and Deschamps,²⁴ Uffelmann,²⁵ Robertson,²⁶ and Stimson.²⁷ Typhoid bacteria, according to Murillo,¹⁰ were still active and virulent from 30 to 36 days after they had been incorporated in garden dirt or after low-hanging fruits had been sprayed with these organisms. On the basis of these data Murillo stated that salads and raw fruits and vegetables were important in the spread of typhoid fever in Spain. Experiments with *Vibrio comma* (*Microspira cholerae*) were equally convincing. Evidences of contamination were reported on water cress by MacDonald.²⁸ Water cress was suggested as the cause of sporadic outbreaks of typhoid fever which are always found but which cannot be traced to any definite source. Bacterial standards of purity have not been established for water cress or other vegetables. Mihaeloff²⁹ also showed the contaminated condition of some fresh vegetables. Coliform bacteria were found in 68 cases, *Eberthella typhosa* in eight, *Salmonella paratyphi* in six, and *Salmonella schottmülleri* in six. *Shigella dysenteriae* and *Microspira cholerae* were present in one case each. Mihaeloff suggested washing of vegetables in flowing water for five minutes and in chlorine solutions.

Escherichia coli on Fresh Vegetables. The position which this organism holds as an indicator of pollution in various foods and beverages prompted Slocum and Boyles³⁰ to determine the incidence and significance of this

organism on vegetables which were irrigated with water of questionable purity or raised on polluted soil. Vegetables irrigated with sewage-polluted water had a considerably higher incidence of coliform bacteria on their surfaces than those irrigated with nonpolluted water. The former harbored from 100 to 10,000,000 cells per 100 grams on all vegetable samples which were irrigated with impure water. Slocum and Boyles then decided to learn the incidence of *Escherichia coli* on market vegetables. *Escherichia coli* was present on 31.5 per cent of samples and coliform bacteria on 78.3 per cent. These organisms were found in higher percentages on vegetables which grow below the ground than on the edible portions growing above the ground. No difference in incidence of these bacteria was observed on vegetables raised on different areas. The question to answer is whether these results indicate that such pathogenic bacteria as *Eberthella typhosa* can also appear on fresh vegetables. That soil bacteria including *Escherichia coli* do not prevent development of *Eberthella typhosa* seems to be indicated by experiments by Pfuhl.³¹ Mair³² found that *Eberthella typhosa* could survive in natural soils in large numbers for about 20 days, and in small numbers for 70 to 80 days. Survival in sterilized soil was said to be much shorter.

Sterilization of Vegetables. Under some conditions, it may be necessary to sterilize vegetables. Different methods have been studied. Champion and van de Velde³³ studied chlorinated lime for this purpose. They gave special attention to *Escherichia coli*, pathogenic bacteria, and the total number of all forms. Chloride of lime showed satisfactory action on vegetables. Lettuce and carrots rinsed in .2 per cent solution were reasonably well disinfected but not sterilized. *Escherichia coli* was destroyed by this concentration and the total number of bacteria was frequently reduced to zero. Herfarth³⁴ also used bleaching powder for ridding vegetables of undesirable bacteria. Matsuoka and Shiraiwa,³⁵ however, believed that the required amounts of chlorine and the times were too long, owing to a rapid consumption of chlorine by the vegetable tissue when the vegetables were cut up. About 500 p.p.m. for 10 hours were required. Surfaces of apples or radishes were effectively sterilized in 30 minutes' exposure to a solution containing 50 p.p.m. of available chlorine. Results of another investigation on the same subject were reported by Suzuki,³⁶ who used chloride of lime in strengths between three and 200 p.p.m. *Eberthella typhosa* was killed in 15 minutes. *Eberthella dysenteriae* and *Vibrio comma* were killed in less than five minutes in solutions having three p.p.m. of available chlorine. Experiments with vegetables showed that *Eberthella typhosa* was not killed in 40 minutes in solutions having 200 p.p.m. of chlorine. This was said to be due to lack of penetration. Such data indicate that chlorine disinfection of vegetables might not yield a safe food in

all cases. This conclusion seems to have been confirmed in Japan by Bannai and Habu.³⁷ They could not satisfactorily disinfect such vegetables as greens, radishes, turnips, and spinach with bleaching powder, irrespective of its concentration or length of exposure.

Potassium permanganate has also been employed for disinfecting vegetables used in salads without cooking. Bernard³⁸ first washed them in clear water and then soaked them for one-quarter hour in a one to 2,000 potassium permanganate solution. He inoculated chopped green salad leaves with *Escherichia coli* and staphylococci and exposed them to the action of various strengths of potassium permanganate for periods of 10, 30, and 60 minutes. The permanganate strengths varied from one to 10,000 to five to 100. Under these conditions, even after one hour, the test organism was recovered. In strengths of over one to 1,000 the appearance of the salad was spoiled. Bernard concluded that this compound could not be used; such conclusion was also reported by Gohar.³⁹

Public Health Significance of Sewage Sludge Used as a Fertilizer. An important factor in epidemiology is the longevity of pathogenic bacteria in nature, for upon such longevity rests the ability of various agents, such as foods, to disseminate communicable diseases. Chief among such agents may be fresh vegetables which are eaten raw. The possibility of such foods causing food-borne infections directs attention to the methods by which they may be infected. Before considering the modes of infection, however, information on the actual presence of *Eberthella typhosa* in sewage and the actual significance of fresh vegetables in disease dissemination should be reviewed.

The nature and origin of sewage would suggest that it would contain *Eberthella typhosa*. This organism might be present even though there were no recognized cases of typhoid fever. The missed case and the carrier make it possible for this organism to be present most of the time. Results of bacteriological examination of sewage have borne out this suggestion. Sir Alexander Houston in several Research Reports from the Metropolitan Water Board reported isolation of *Eberthella typhosa* from sewage. Wilson and Blair⁴⁰ showed that Belfast sewage contained *Eberthella typhosa* constantly over a period of three years. One milliliter of sewage contained at least one cell of *Eberthella typhosa*. Gray⁴¹ found *Salmonella schottmülleri* in seven of 20 specimens of sewage from the city of Edinburgh. Seventeen of the samples, including all of the positive ones, were from one district. Gray used the Wilson and Blair direct-plating method and reported it to be superior to enrichment methods. Further review of literature on this subject need not be attempted here.

The significance of fresh vegetables is related to the use of night soil, sewage, and sewage sludge as fertilizer. This subject has been significant with respect to sewage farming, in which an attempt was made to utilize

the constituents of domestic sewage as fertilizer. In some cases the water was desired. From the beginning, health officers looked with suspicion on the practice and rightfully so, if for no other reason than decency. It is true that in some oriental countries human excrement is used as fertilizer but such a practice need not be permitted in this country. The primary problem of sewage disposal is to get rid of the waste matter. The temptation in sewage farming has been to let fertilization of crops become the paramount object with less and less attention to the sewage disposal feature. Among many objections and technical difficulties is that which is before us in this discussion—the possible health hazards which may be involved in the use of fresh vegetables which have been fertilized with sewage or sewage sludge. Any method of sewage treatment which results in sludge presents serious problems of sludge disposal for some communities.

Good epidemiological evidence seems to exist in the literature to the effect that fresh vegetables may and have caused communicable diseases and that the sanitary condition of the soil from which they are harvested, is important. Bundesen⁴² believed that more attention should be given to raw foods. Water cress, on account of the conditions under which it is cultivated, was viewed with considerable suspicion. It is well known that *Eberthella typhosa* may survive for long periods in the soil. Murillo¹⁰ found these organisms to be active and virulent in garden dirt after 30 to 36 days. In sterile sand, they survived for 55 days. Galvagne and Calerin⁴³ studied this question in a privy vault, in a barrel, and in soil. The organism survived in the privy vault for 30 days, in the barrel 25 days, and in feces spread upon soil, after 10 days on the surface and 40 days in the deeper layers. Mair³² could isolate the organism after 84 days from soil. Levy and Kayser⁴⁴ observed a survival period of over five months in a naturally infected privy vault. This included 14 days during which the infected feces had lain as fertilizer in a garden. Firth and Horrocks,⁴⁵ after a very comprehensive study, concluded as follows:

1. That there was no evidence to show that the *Eberthella typhosa*, when placed in soil, displays any disposition or ability to either increase in numbers or grow upward, downward, or laterally.

2. That *Eberthella typhosa* can be washed through at least 18 inches of soil by means of water, even when the soil is closely packed down and no fissures or cracks are allowed to exist.

3. That *Eberthella typhosa* is able to assume a vegetative existence in ordinary and sewage-polluted soil and survive therein for varying periods, amounting in some cases to as much as 74 days.

4. That the presence or absence of organic nutritive material in the soil appears to be a largely negligible factor, since *Eberthella typhosa* can survive in a soil indifferently well, whether it be an organically polluted soil or a virgin soil, and whether it receive dilute sewage or merely rainwater.

42. Bundesen. 1925. J. Amer. Med. Assoc., 85, 1285.

43. Galvagne and Calerin. 1908. Ztschr. Hyg. u. Infektionskrank. 41, 185-208.

44. Levy and Kayser. 1903. Centbl. Bakt., 33, 489.

45. Firth and Horrocks. 1902. Brit. Med. J., II, 936-943.

5. That an excess or great deficiency of moisture in soils appears to be the dominant factor affecting the chances of survival of the enteric bacillus in, or at least the possibility of recovering it from, soil.

6. That from fine sand allowed to become dry, *Eberthella typhosa* can be recovered on the 25th day after inoculation.

7. That from fine sand, kept moist with either rain or dilute sewage *Eberthella typhosa* cannot be recovered later than the 12th day after fouling; this inability to recover the organism is due probably not so much to its death as to its being washed down into the deeper sand layers by liquids added.

8. That in peat, *Eberthella typhosa* appears to die out rapidly, as the microbe cannot be recovered from it after the 13th day; but this soil is so porous that it is quite possible the microorganisms were washed down into the deeper parts and consequently were not recoverable from the place of inoculation.

9. That from ordinary soil kept damp by occasional additions of rain-water *Eberthella typhosa* can be recovered up to and on the 67th day.

10. That from a similar soil kept damp by occasional additions of dilute raw sewage, *Eberthella typhosa* is recoverable up to the 35th day.

11. That from a similar soil kept damp by occasional additions of dilute sterile sewage the *Eberthella typhosa* is recoverable up to the 74th day.

12. That in a similar soil, after heavy rainfall, *Eberthella typhosa* at once disappears from the surface layers.

13. That from a similar soil, allowed after inoculation to become so dry as to be readily blown about as dust, the enteric typhoid infective material can be readily translated from dried soil and sand by means of winds and air currents.

14. That in a sewage-polluted soil recovered from beneath a broken drain, *Eberthella typhosa* is able to survive up to the 65th day.

15. That *Eberthella typhosa* is able to survive in surface soil on exposure to 122 hours of direct sunshine, extending over a period of 22 consecutive days. That from a piece of infected serge *Eberthella typhosa* is recoverable after the fabric has been exposed to 50 hours of direct sunshine spread over a period of 10 days.

Results from an investigation by Kligler⁴⁶ are also pertinent to this discussion. He made observations to determine danger of soil pollution and its relation to the spread of intestinal diseases. He reported that bacteria causing typhoid fever and dysentery succumb rapidly in nature. Both organisms died out in one to five days in septic tanks. The survival period of these organisms in soil was greater than in badly polluted materials. In moist natural soil with a pH of 6.6 to 7.4 typhoid and dysentery bacteria were recovered up to 70 days. In the same soil dry, they were not recovered after two weeks. It is quite obvious from Kligler's work that the character of the soil and other factors greatly influence the results that would be secured.

46. Kligler. 1921. Rockefeller Inst. Med. Res. Monog. No. 15, p. 75.

Longevity of pathogenic bacteria in soil is influenced by different factors. Among the important ones are character of the strain used, hydrogen-ion concentration of the soil, nature of competing bacteria, amount of moisture, penetration of light and air, and others. Sufficient data have been recorded in the literature to justify the conclusion that polluted soil may infect vegetables grown on it. Whether the problem is serious, however, depends on many factors. Any material, therefore, which may contribute pathogenic bacteria to soil becomes of considerable sanitary significance. Sewage sludge is in this category, because sewage from which it comes is known to contain pathogenic bacteria.

That sewage sludge should be applied with considerable caution to land on which crops to be eaten raw are to be grown has been recognized for many years. Wolman,⁴⁷ however, stated that if it is held in a sludge digestion tank for a period of not less than 10 days, its application to soil may be practiced without detriment to public health through the possible dissemination of vegetable-borne diseases. Wolman suggested regulations that would prevent delivery to farmers of sludge which had been digested for less than 10 days. He further suggested that the sludge should be used on ground only before crops are planted and not sprinkled over or brought into direct contact with growing vegetables. The origin and type of the sludge undoubtedly has considerable bearing on the results which may be secured. Whether Wolman's conclusions would apply to all types of sludge could be determined only by comprehensive investigations. New methods for isolating bacteria have been developed in the past few years. Use of these methods might reveal the presence of bacteria where the older methods gave negative results. The later paper by Ruchhoft⁴⁸ would suggest that it is now time for more work on the subject.

Ruchhoft reported isolation of *Eberthella typhosa* from activated sludge. Investigations of artificially inoculated aeration mixtures were then made. Five and one-half hours' aeration caused a decrease in viable *Eberthella typhosa* cells from 750,000 to 103,000 per milliliter. Four strains of *Eberthella typhosa* were used in experiments on longevity in activated sludge. At 20 to 22.2°C. (68 to 72°F.) one of the strains died rapidly; two others survived for eight to 10 days; the fourth, the Rawling's strain, was isolated after 13 to 14 days. Ruchhoft concluded that "wet activated sludge cannot be considered innocuous. At times it may be quite infectious. Caution should be observed when it is used as a fertilizer for truck gardens."

The application of sewage sludge to soil on which vegetables that may be eaten raw are grown, should be practiced with caution. While results of longevity studies on pathogenic bacteria in sludge would probably be greatly influenced by the nature of the sludge and the conditions under which it is stored and handled, sufficient data have been recorded to indicate the presence of viable *Eberthella typhosa* cells in sludge. At best the sludge should be added to the soil in the late fall, winter, or early spring.

47. Wolman. 1924. Engin. News-Rec., 92, 198-202.

48. Ruchhoft. 1934. Sewage Works J., 6, 1054-1057.

Wolman's advice that it should not be added to growing crops is probably sound. Sanitary districts and others concerned with the sale of sewage sludge to farmers might well consider the possible health hazards involved.

The Committee on Sewage Disposal of the American Public Health Association ⁴⁹ recommended that fresh sewage sludge should be used only on forage crops and ploughed in promptly after application. It was recommended that sludge not be added to root crops or low-lying leafy vegetables which are eaten uncooked.

Penetration of Vegetables by Microorganisms. There is very little evidence that bacteria are able to penetrate very far into plant tissue. Careful experiments on this subject seem to indicate that bacteria die out rapidly when introduced into plants. Mills *et al.*,¹⁸ after a study of the literature, were in accord with the above statement. They found that particulate matter corresponding in size to bacteria and protozoan cysts did not freely penetrate the substance of either fruits or vegetables; such matter remained on the surface or attached to portions which are usually removed when the vegetables are prepared for the table. Neither was the cut end penetrated to any appreciable extent. The skin of fruits and vegetables, then, like the skin of animals, is a barrier preventing infection. However, injured fruits and vegetables allowed the entrance of bacteria. Mills stated that bacteria might endure under such conditions for seven to 42 days. Data from experiments by Clauditz ⁵ and others on this subject are given in the paragraph above.

Preservation of Vegetables by Dehydration. The object of drying vegetables is to reduce the water content to such a point that bacteriological and chemical changes are prevented. Nichols, Powers, Gross, and Noel,⁵⁰ who made an extensive study of commercial dehydration, stated that fruits and vegetables with low amounts of sugar should not have more than five to 10 per cent of moisture; moisture in products with much sugar should not exceed from 15 to 20 per cent to assure best keeping qualities. Looking at the matter from another angle dehydrated foods may be considered as concentrated solutions in that there is a large amount of organic material and a very low amount of water. Prescott ⁵¹ stated that dehydrated vegetables generally contain less than 10 per cent of water. Cruess ⁵² described the dehydration of fruits and vegetables in California. *We are indebted to the investigations of Prescott *et al.*⁵³ for much of our knowledge on the bacteriology of dehydrated foods. The bacteria on such foods are made up of those which have survived the process and those which have been contributed during handling and packing. Prescott found that few, if any of the foods, were sterile. During long storage the number was reduced slowly. Mold spores were commonly present but yeasts were invariably absent. Bacteriological data reported by Prescott indicated a variable bacterial content. One sample of mixed vegetables had a plain agar count of

49. Engin. News-Rec. 119, 906.

50. Nichols *et al.* 1925. U. S. Dept. Agr. Bull. 1335.

51. Prescott. 1920. J. Bact., 5, 109-125.

52. Cruess. 1921. Amer. J. Pub. Health 11, 6-12.

53. Prescott, Nichols, and Powers. 1922. Amer. Food J. 17, 11-16.

1,600,000, a glucose agar count of 2,000,000, and a litmus lactose agar count of 2,000,000. Prescott also inoculated vegetables heavily with some of the undesirable organisms. When these vegetables were dried, most of them were killed. Prescott, Nichols, and Powers published further data on the subject. Moisture content was found to be one of the important factors and if its concentration was kept below a critical concentration the microorganisms did not change.

Clague⁵⁴ examined samples of dried vegetables which were received from manufacturers. The counts were determined on the gram basis. Numbers of microorganisms were much higher than on fruits, the numbers exceeding 500,000 per gram except on dill and garlic. Molds and yeasts were scarce on vegetables.

Prescott's⁵¹ Method for Determining the Number of Microorganisms in Dried Foods. Ten grams of the sample, well broken up with aseptic precautions, were weighed into a tared sterile dish and later transferred to an Erlenmeyer flask containing 200 ml. of sterile tap water. After thorough mixing in order to get all of the particles wetted, the sample is placed at 37°C.(98.6°F.) for two hours to allow the tissues to come back to normal condition and permit an easy separation of bacteria. At the end of this time the sample is again agitated and aliquot portions are removed for culture. Plate cultures with glucose agar should be used. Incubation should be at 37°C. for 40 to 48 hours.

The microorganisms of dried foods are probably not different from those found in other foods. The flora is probably predominately sporulating since the heat treatment is sufficient to destroy the vegetating forms. Since bacteria require so much water, they probably do not function much in the spoilage of dehydrated vegetables. Insect infestation is a common cause of spoilage. The moth *Plodia interpunctella* is one of the commonest moths found in dehydrated vegetables. It is also responsible for the spoilage of other foods, such as cornmeal, oatmeal, and numerous ground breakfast foods. The infection is said to have its origin in the adult laying its eggs on the dehydrated food after drying and before it has been packed into the final container. Consequently, the packing rooms should be assiduously guarded from the moths.

Clague's⁵⁴ Method for Determining the Bacterial Content of Dried Vegetables. Two 10-gram portions of each sample are weighed into two wide-mouth dilution bottles containing 90 ml. of sterile water. The samples are shaken 100 times by hand and further dilutions made. Duplicate plates are made from each dilution using tomato agar, plain nutrient agar, and dextrose agar. These plates are incubated at 30°C.(86°F.) for 48 hours.

FROZEN VEGETABLES

A wide variety of vegetables are preserved by quick-freezing. The general bacteriological problems have been discussed in Chapter 1 as well as the effect of freezing on the microorganisms causing food poisoning. Based on considerable experience, Tressler⁵⁵ mentioned three criteria for judging quality of frozen vegetables: bacterial count, catalase and peroxidase tests, and determination of ascorbic acid content. A bacterial count under 80,000 per gram shows that the product was blanched at a high enough temperature to destroy all of the bacteria on the surface of the vegetables, that the blanched product was quickly cooled in clean water, and that it was properly handled before and after freezing. Tressler stated

54. Clague. 1936. Food Research 1, 45-59.

55. Tressler. 1938. Refrig. Engin. 36, 319-321.

that careless handling would result in a product with at least 100,000 or even 200,000 bacteria per gram. Lochhead and Jones⁵⁶ observed a wide variation in bacteria content of frozen vegetables soon after packing. During storage, however, this was obliterated. Coliform bacteria decreased during the first six weeks of storage to an insignificant number, while anaerobic sporeforming bacteria persisted somewhat. Defrosting at room temperature resulted in a marked increase in bacteria content while defrosting in the refrigerator resulted in a much smaller increase. Smart⁵⁷ reported that defrosted vegetables were unfit for food after 24 hours at 30°C. (86°F.). The types of bacteria in commercially frozen vegetables were without any significance so far as health is concerned. In this connection Berry⁵⁸ gave lactic acid-producing bacteria considerable importance because they survived freezing well and would develop conditions unfavorable to *Clostridium botulinum*.

General statements probably should not be made about the bacteria content of various frozen vegetables. The method of preparation and the soil from which they are harvested would have some influence.

Commercial machine-shelled peas show high infection with bacteria.⁵⁹ Blanching does not sterilize peas. They should be frozen as soon as possible after blanching.

Spoilage of quick-frozen vegetables may be of different types caused by various microorganisms. Bacteria have been found to be the main cause of spoilage in vegetables, while yeasts and molds may be the cause in fruits. Souring of quick-frozen vegetables was attributed by Sanderson and Fitzgerald⁶⁰ to *Streptococcus fecalis* which was believed to exist in the pod and on the kernels of corn examined aseptically. They believed that frozen vegetables would be sour to the point of inedibility before microorganisms forming enterotoxins could develop. Whether this would be the case must be determined experimentally.

Survival of Bacteria in Frozen Vegetables. Results of investigations in various parts of the United States and with various frozen vegetables indicate wide variations in numbers and types of microorganisms. Reasons for this are obvious since the flora of the raw products and processing methods and conditions would have considerable effect.

Smart and Brunstetter⁶¹ reported that organisms in only three genera failed to survive freezing for three to 15 months when the foods were held at -9.4°C. (15°F.). All molds and yeasts survived. While lima beans were a good medium for development of microorganisms, the authors believed that no difficulty need be anticipated with keeping quality or

healthfulness. Smart ⁶² found approximately 10,000 to 300,000 microorganisms on fresh washed mushrooms. Steam blanching resulted in marked reduction in the number of viable bacteria. The bacteria in four packs were reduced from 275,000 to 720 per gram by blanching for five minutes in steam. About two-thirds of these surviving bacteria died out during six months' storage of the mushrooms in the frozen state. Members of the coliform group survived blanching but were not present after six months' freezing at $-9.4^{\circ}\text{C}.$ ($15^{\circ}\text{F}.$). Sporeforming bacteria, molds, and yeasts did survive. Smart reported a marked ability of yeasts to survive low temperatures. Because of survival of many types of microorganisms, Smart advised against eating frozen mushrooms in the raw or semiraw state.

Bacteriological studies on freezing peas, by Diehl, Campbell, and Berry ⁶³ showed that shelled raw peas may harbor 1,000,000 microorganisms per gram, and that after about six hours at $21.1^{\circ}\text{C}.$ ($70^{\circ}\text{F}.$) the number increases rapidly. While scalding at 93.3 to $98.9^{\circ}\text{C}.$ (200 to $210^{\circ}\text{F}.$) for one minute kills some 99 per cent of the microbial flora, scalded peas permit very rapid growth of survivors and spoil fully as readily as raw peas. Microbial growth in both raw and scalded peas is largely prevented for 48 hours by a temperature of $0^{\circ}\text{C}.$ ($32^{\circ}\text{F}.$). The lower limit for microbial growth appears to be between -9.4 to $-6.7^{\circ}\text{C}.$ (15 to $20^{\circ}\text{F}.$). The usual storage temperature of frozen-pack peas of about $-17.8^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$) reduces the microbial population greatly in a few months. According to Lochhead and Jones, ⁶⁴ micrococci (including staphylococci) comprised a much larger percentage of the organisms in frozen than in freshly packed products. Though $20^{\circ}\text{C}.$ ($68^{\circ}\text{F}.$) permitted development of greater numbers than 37 or $4^{\circ}\text{C}.$ (98.6 or $39.2^{\circ}\text{F}.$), organisms developing at $37^{\circ}\text{C}.$ were proportionately the most resistant and those developing at $4^{\circ}\text{C}.$ were the least resistant to freezing. This is due to the fact that as the temperature of incubation is increased micrococci comprise a higher proportion of the organisms developing. Attention is directed to the importance of the Micrococcus group of bacteria in relation to the proper handling of frozen vegetables. The microorganism content of fresh spinach and kale used by Smart and Brunstetter ⁶⁵ was high, the lowest count being 1,200,000 organisms per gram. Scalding, freezing, and storage at $-9.4^{\circ}\text{C}.$ ($15^{\circ}\text{F}.$) for about one year reduced this count more than 99 per cent. The microbial content of the frozen greens was characterized by a great diversity of types (genus names and some names of species are listed for organisms frequently isolated from fresh and frozen spinach and kale). While the counts were low in numbers and types present were those ordinarily found in fresh vegetables and in no way affect the wholesomeness of the product, there were enough viable microorganisms in the frozen greens to cause spoilage in a few hours at room temperature. When proper care is taken in handling good-quality spinach and kale and when prompt cooling

65. Smart and Brunstetter. 1937. *Idem* 2, 151-163.

and freezing are practiced, high microbial counts should not be encountered in the frozen packs of these products.

More results were reported by Smart ⁶⁶ on peas, beans, and sweet corn. Smart made a comprehensive study of the microbial content, quantitative and qualitative, before and after freezing of 18 varieties of peas, 35 varieties of sweet corn, 14 varieties of green and wax beans, and eight varieties of lima beans, all grown in the East. The microbiological examination included studies on both the fresh and frozen vegetables except for peas which were studied only in the frozen state. The microbial content of the fresh vegetables used in this experiment was high and varied considerably in different lots. Scalding and storage of these vegetables at -17.8°C . (0°F .) for five to seven months reduced the microbial content of sweet corn 94.6 per cent, green and wax beans 99.8 per cent, and lima beans 97.2 per cent. The average microbial content of frozen sweet corn was higher than that of the other vegetables studied. This might have been due in part to a higher initial contamination, which was associated with ear-worm infestation in the fresh corn; or to the greater protection sweet corn afforded the microorganisms which contaminated it, against the killing effects of low temperature, than was afforded by either green or lima beans. The sugar content, which is higher in sweet corn than in green or lima beans, was suggested as a possible protective factor. In spite of the great reduction of microorganisms resulting from scalding and freezing storage of vegetables the frozen products contained sufficient viable forms to bring about spoilage in a few hours at room temperature. The types of microorganisms frequently isolated from both fresh (except peas) and frozen vegetables are listed and were found to be those normally present on vegetables which would in no way affect the healthfulness of the frozen products provided they were kept frozen until they were used. Frozen foods, which are still essentially fresh foods, should be subjected to at least the same care in observing proper sanitary control during their preparation and storage as has been found necessary in handling fresh foods.

Nickerson's ^{66a} Modified Little Plate Method for Counting Bacteria in Frozen Vegetables. The Frost little plate procedure was modified by Nickerson to aid in plant sanitation in packing frozen foods. Three distinct changes were made in the procedure as given in Chapter 6.

1. The incubation period of four to eight hours was lengthened to 16 hours.

2. A new staining procedure was used.

3. A slide was developed which greatly facilitated the work.^{66b} This slide limited the culture to a definite area, prevented washing off of the agar film during staining, and allowed more thorough mixing of culture and medium. Errors, resulting from the use of a glass marking pencil

66. Smart. 1937. Food Research 2. 515-528.

66a. Nickerson. 1943. Food Research.

66b. The slide was developed by M. G. Hallenback, formerly with the Birdseye Laboratories at 3 Commercial Street, Boston, Mass.

to confine the culture to a definite area and caused by mixing of pencil wax and culture, were entirely eliminated by use of the new slide.

The new slide was provided with a central elevated portion, of definite area, which served as the surface supporting the culture. Slides of this type were made either by grinding away the area around the raised portion or by fusing a piece of glass, of definite area, upon a larger glass strip.

A number of the special slides are cleaned in dichromate-sulfuric acid solution, thoroughly rinsed with water, wiped dry, and sterilized with dry heat in a closed metal container.

Small batches of nutrient agar are sterilized in homeopathic vials plugged with cotton. The vials are heated to melt the agar, after which the cotton plug is replaced with a sterile rubber stopper fitted with a medicine dropper and bulb. During preparation of cultures, the agar is kept molten by suspending the vials in a beaker of water kept at 45°C. (113°F.). Extension clamps are used to hold the vials.

Ten grams of the sample to be examined are placed in 90 ml. of sterile dilution water and thoroughly shaken. A sterile slide is placed on the warming table (metal plate regulated to 45°C. by clamping on a ring stand above a hot plate) and .1 ml. of the dilution water is delivered to the raised portion. The measuring pipette used (capacity $\frac{1}{10}$ milliliter) is lined with dilution water several times by filling and emptying the pipette, and the lower portion is wiped with a sterile kleenex before the culture sample is delivered. Four drops of molten nutrient agar (33.5 grams bacto-nutrient agar to 1,000 ml. of distilled water) are then placed on the raised portion of the slide and the material thereon mixed. Mixing is accomplished by running a sterile wire through the culture 15 times, first backwards and forwards then from right to left to right. The culture is spread to the edges of the raised portion by slanting the needle and following the edge of this area.

The slides, prepared as indicated in the foregoing, are marked for identification and placed in a moist chamber for incubation. After 16 hours' incubation at 25°C. (77°F.) cultures are removed, heated on a hot plate at about 80°C. (176°F.) until dried, treated with a one-per cent aqueous ferric sulfate solution for 20 seconds, washed, and treated with a .5-per cent aqueous solution of hematoxylin for 15 to 30 seconds. The agar film is then washed and dried.

The prepared slides are examined with the microscope, using a 16-mm. objective, to detect bacterial colonies. A blood cell counter greatly facilitates this work, since it provides means of recording both number of fields and number of colonies counted with minimum trouble.

Since .1 ml., from the equivalent of 100 ml. of dilution water, containing the bacteria from 10 grams of product, was used, the number of bacteria per gram of product is determined by the following formula:

$$100 \times \frac{\text{Area of little plate}}{\text{Area of microscopic field}} \times \frac{\text{Number of colonies found}}{\text{Number of fields counted}}$$

Since 100 fields were counted on all slides, the formula resolved to:

$$\frac{\text{Area of little plate}}{\text{Area of microscopic field}} \times \text{Number of colonies found.}$$

VEGETABLE JUICES

These products were developed largely on account of the success attained by fruit juices. They have never been as popular on account of carelessness in manufacture and over advertising. Some were hailed as foods while others were looked upon merely as beverages. The term "vegetable-wines" was used by a few of the pioneers. Some of the early efforts to prepare these products have been described by Cruess *et al.*⁶⁷ and Tressler.⁶⁸ Since vegetable juices are nonacid in character, some care must be used in processing them in glass jars or cans.

Two cases of typhoid fever traced to freshly prepared carrot juice prompted Geiger⁶⁹ to investigate the preparation of such products. Freshly prepared carrot juice was found to be slightly acid, pH 6.5 to 6.7. The bacterial content of fresh juice varied between wide limits, the greater number of organisms coming from the surface of the carrot and from steps in processing. Geiger believed that more care in washing and preparing the carrots for juicing should result in a virtually sterile product. Using elaborate precautions, however, a minimum count of 2,800 colonies per ml. was secured. The maximum count observed was three million colonies per ml. It is difficult to evaluate these figures since no standards exist for vegetable juices. Furthermore, Geiger believed that satisfactory standards could probably not be established.

The Department of Public Health of San Francisco passed regulations for pasteurization of vegetable juices. It was recognized, of course, that such regulations would not put completely sterile juices on the market but would greatly reduce the bacterial content and destroy pathogenic bacteria if they should be present. Experiments show that coliform organisms were usually eliminated and always sharply reduced. Experiments with a freshly isolated strain of *Eberthella typhosa* in all cases, even with liberal inoculations, showed that *Eberthella typhosa* did not die in the raw juices, indicating that it probably was not germicidal. Extended investigation would be needed to demonstrate conclusively that pasteurization at 60°C. (140°F.) for 30 minutes is not adequate and that 61.1 or 61.7°C. (142 or 143°F.) for 30 minutes would be preferable as a lower limit.

Chlorination was not found to be satisfactory. Even with carefully scrubbed hands, with carrots immersed in 200 p.p.m. chlorine, and with the use of completely sterilized apparatus, the bacterial count was appreciable and spoilage was not delayed. Despite these results, Geiger believed that chlorine sterilization might be given more study.

CHAPTER 16

MICROBIOLOGY OF TOMATO PRODUCTS

Tomatoes and tomato products are widely used in most countries. The fruit itself is used fresh or canned and has been shown to be a good food. Many tomato specialties are also available which add to the flavor of other foods. Various bacteriological problems arise in preparation of these products, and those people experienced in the use of the microscope are called on to determine whether satisfactory raw materials have been used. The laboratory procedure involved, known as the Howard mold-count method, is discussed later in this chapter. It has had a large part in improving tomato products and has won the confidence and respect of those processors who desire to pack only high-grade products. Among the many publications which have been issued on tomato products, that by Bigelow, Smith, and Greenleaf¹ is especially useful.

CANNED TOMATOES

Owing to the fact that tomatoes are generally sufficiently acid, less trouble has been experienced in preserving them than most other foods. This is indicated by lower cooks used in processing as well as fewer outbreaks of spoilage.

Strict enforcement of regulations by government food-control officials has made it necessary for canners to devote special attention to sorting and trimming in order to avoid trouble. Decayed portions owing to several types of rot must be removed if the finished product is to comply with the regulations. If the packer uses sound, ripe fruit a high-quality product will be obtained which will easily meet the new government tolerance of not over 50 per cent of microscope fields showing mold.

After careful preparation in the canning factory, tomatoes are filled into various sized cans which are carefully exhausted before closing. If this is not done difficulties of "swells" and "springers" may develop later.

Processes for canned tomatoes have been published by Bigelow.² These processes have been found to be satisfactory if cooling is adequately carried out. Heat-penetration studies on canned tomatoes have been reported by Magoon and Culpepper³ and by Bigelow, Bohart, Richardson, and Ball.⁴ The latter investigators stated that tomatoes packed together in such a manner as to interfere with the free movement of convection currents materially influenced heat penetration. Rotation of the cans makes it much easier for heat to penetrate. Canned tomatoes are cooled by two different procedures—air-cooling and water-cooling. The former is slower than the latter, which means that the temperature of an air-cooled can of

1. Bigelow *et al.* 1941. Tomato Products, Pulp, Paste, Catsup, and Chili Sauce. Natl. Canners Assoc., Washington, D. C., Bull. 27-L, Revised.

4. Bigelow *et al.* 1920. Natl. Canners Assoc. Bull. 16-L.

tomatoes will continue to rise for some time after the cans have been removed from the cooker. Heat is removed from the can much more quickly by water cooling. It should be pointed out that the process must be increased if water cooling is practiced.

Experience of the industry indicates that the center of the can of tomatoes should be brought to 87.8°C. (190°F.) if the cans are water-cooled, and to 76.7°C. (170°F.) if they are air-cooled. Some of the confusion over processing temperatures has been due to the two methods of cooling. Air-cooling is less efficient than water-cooling and the temperature continues to rise in the can after it has been removed from the bath consequently water-cooled cans must be cooked a little longer or at a higher temperature. The real object of processing canned tomatoes is to attain a minimum temperature which will insure sterilization. Cannerymen are frequently tempted to lower process time and temperature in an attempt to secure a product with better quality. Siegel⁵ observed that a 45-minute process gave a high-grade product and that it was hazardous to reduce processes.

Types of Spoilage in Canned Tomatoes. Canned tomatoes are not subject to much spoilage. The chemical and physical nature of the product makes sterilization relatively easy. They have an appreciable hydrogen-ion concentration which aids materially in their sterilization. Generally non-sporulating bacteria are found to be present. This is indicated also by the fact that the process times and temperature are much lower than those used for other foods.

Hydrogen Swells. These result from attack of the metal of the can by the acids in the fruit. Hydrogen swells are usually sterile when subjected to bacteriological examination.

Bacteriological Swells. The organism, *Lactobacillus lycopersici*, which causes this spoilage is discussed in a subsequent paragraph in this chapter. This organism is probably not the only one which may cause this type of spoilage, but it is among the most important.

Flat-Sour Spoilage. This spoilage is known in the trade as "flat-sour" spoilage although it is probably a misnomer. Bacteria have been isolated which materially alter the flavor of canned tomato juice and tomatoes. The microbiology of this spoilage is discussed under Tomato Juice later in this chapter.

Thompson⁶ recommended incubation of samples to determine the efficiency of the process given canned tomatoes. He believed that such samples should be collected systematically each day.

TOMATO JUICE

This is one of newer tomato specialties which now enjoys wide acceptance by the public. Nothing is added to the fresh juice except salt. In view of the fact that it is a product, color and flavor of which are most important, great care is exercised to secure the right variety of tomatoes

5. Siegel. 1942. *Canning Age*, Jan. 1942.

6. Thompson. 1928. *Canning Age*, Convention Digest, 256-258.

and to pick them just when they make good juice. If they are picked too green, color suffers; and if they are picked too ripe, the flavor is not good. This product was defined a few years ago by food and drug control officials as "the unconcentrated, pasteurized product consisting of the liquid with a substantial portion of the pulp, expressed from ripe tomatoes with or without the application of heat and with or without the addition of salt." Under the Food, Drug and Cosmetic Act of 1938, a newer definition will probably be heard.

The manufacture of this product has reached a high level in America today, owing largely to results of scientific investigations. These have resulted in a product with good flavor and color and one rich in the vitamins present in natural tomatoes.

Processing Tomato Juice. Tomato juice is generally processed in boiling water under conditions which will bring the center of the can to 82.2°C. (180°F.). Agitation during processing has been found to increase markedly the rate of heat penetration into the can. Under some conditions the center of the can should reach 87.8°C. (190°F.) in order to allow satisfactory sterilization. In view of possible presence of relatively heat-resistant spoilage bacteria in tomato juice, trend in processing tomato juice has been to raise the temperature instead of lower it. Wessel and Benjamin⁷ studied the problem with experimental packs and stated that "flash" processing in a tubular heat exchanger for a time and temperature equivalent to the thermal death-time of the contaminating organism, rapidly cooling to 87.8°C. (190°F.) before filling and processing the closed cans for a brief time at 100°C. (212°F.) to destroy nonresistant bacteria which might enter during filling, might be used commercially. Merrill cautioned against lowering processes for tomato juice when it is indicated that higher processes have little appreciable effect on general quality. He pointed out that lower process times and temperatures do not have the effect on quality that is attributed to them. His statements were based on results of experiments using both high and low filling temperatures and high and low processes. The low temperatures ranged from 63.9 to 68.3°C. (147 to 155°F.), while the high temperatures ranged from 76.7 to 93.3°C. (170 to 200°F.). As far as quality was concerned experienced canning technologists could find little difference between tomato juice processed at 100°C. (212°F.) for 20 to 35 minutes or at 112.8° (235°F.) for from 10 to 30 minutes.

Flat-Sour Spoilage of Tomato Juice. This is a bacterial defect of tomato juice which has been encountered since the juice has been packed, according to Pearce and Ruyle.⁹ Although the spoilage has been known for many years, it has had more attention since Berry¹⁰ discovered the causal organism to which he gave the name *Bacillus thermoacidurans*. Berry described the organism quite thoroughly. Only those characteristics of interest to processors of tomato juice will be given here. A concentration of 10

10. Berry. 1933. J. Bact., 25, 72.

million spores per ml. gave a span over one logarithmic cycle on semi-log paper of 14.5°F. in tomato juice pH 4.5 and 17°F. in phosphate buffered water pH 7.0 with an extrapolated "F" value (destruction time in minutes at 250°F.) of .33 minutes in tomato juice and 3.8 minutes in phosphate buffered water.

This organism was isolated from off-flavored canned tomato juice. While the spoilage eventually ends in "flat-sour" type of spoilage an off-flavor is noticeable some time before a change in pH occurs. Berry believed that soil was the source of the organism.

Results of observations on packs of tomato juice (2,058 cans) and other acid foods (132 cans) showed a decrease in pH of all cans. The off-flavor appeared more quickly at 37°C. (98.6°F.). Heavier inoculations produced higher incidence of spoilage. Processing for 10 minutes at 100°C. (212°F.) gave 28 per cent more off-flavored cans than processing for 20 minutes at this temperature. *Bacillus thermoacidurans* produced the off-flavor in Indiana tomatoes but not in California tomatoes.

As the name of the spoilage indicates, the cans do not swell and considerable experience indicates slight if any loss of vacuum. This makes it impossible to separate spoiled from unspoiled cans because deterioration is not apparent until the can is opened and the contents examined. The organism, *Bacillus thermoacidurans*, is a little fastidious in its growth habits as revealed by results of investigations by Stern, Hegarty, and Williams.¹¹

Non-thermophilic spore-forming anaerobic bacteria have been found as causes of spoilage in certain acid canned foods (pineapple and tomatoes). *Clostridium pasteurianum* was isolated from canned pineapple by Spiegelberg, Townsend, and Woerz and Lenane.^{11a} The latter found them in canned tomatoes from different sections of the country.

Pearce and Ruyle⁹ believed that multiplication in the canning plant was the crux of the problem of control. Consequently, cleanliness and elimination of all sources of contamination are first among whatever efforts are made to control the trouble. Pearce¹² again emphasized the seriousness of this type of spoilage. He reported discovery of viable spores of the spoilage organism in cans which had not undergone change in flavor at the time of sampling. Such results raised the question as to the significance of these dormant spores and what conditions of storage might favor their development. Williams¹³ also recognized the necessity of strict cleanliness in the canning factory in order to reduce possibilities of contamination. While regular bacteriological technic has been used in most of the work on this trouble, Cameron¹⁴ suggested another method. A few cans of tomato juice were taken from the line at the beginning of the day's pack and another set after the plant has been running for two or three hours. We may quote Cameron for details:

11. Stern, Hegarty, and Williams. 1942. Food Research 7, 186-191.

11a. Woerz and Lenane. 1943. The Canner, Feb. 6, 1943, 11-12; 24.

12. Pearce. 1940. The Canner 90, No. 12, Pt. 2, Convention Issue, 49-51.

13. Williams. 1940. Idem 48-49.

14. Cameron. 1935. The Canner, July 20, 1935.

“Sampling Procedure. A. Take 24 cans daily at the beginning of the pack or as soon thereafter as the filling temperature reaches 82.2°C.(180°F.) or 87.8°C.(190°F.). Under no circumstances should samples be taken before 180°F. is reached, because it is necessary to destroy all bacteria not in the spore form. Invert the cans and allow them to air cool. Apply suitable codes and set aside for daily observation.

“B. Take 24 cans after the line has been operated for from two to two and one-half hours without extended shut-down periods. Invert cans and treat otherwise as indicated under “A.” When the samples are taken, make certain that the filling temperature is at least 180°F.

“C. If there are two or more lines, it is not suggested that 24 cans be taken from each line. A total of 24 cans from all lines at each sampling period should be sufficient.

“Observations for Spoilage. Make daily observations. If spoilage contamination is high, a significant number of swells should appear within two or three days, although, in some instances, it is possible that only flat-sour spoilage may occur. At the end of ten to fourteen days, open flat cans and taste to determine whether there is flat-sour spoilage. If no swells occur in samples from the first period, open one-half the number of the samples at the end of five days to determine whether flat-sour spoilage has occurred. Record the occurrence of swells and flat sours on a card especially drawn up for that purpose.

“Interpretation of Results. If spoilage is low (below 25 per cent) in samples from the first sampling period and materially lower or absent in the second sampling period, the condition of the equipment and the efficiency of the clean-up may be regarded as satisfactory.

“If there is high spoilage in the first samples followed by low spoilage or its absence in the second samples, there is the indication that there has been an overnight development of spoilage bacteria which infects the product during the first part of the day's run. In other words, this contrast means that at the start of the pack there are bacteria in the equipment which are gradually washed out by the tomato juice. The cleaning of the equipment should be carefully supervised, and all utensils and pipe lines should be thoroughly flushed with water before beginning the day's run. Hot water may be used for flushing and is preferable to cold water because it will serve the double purpose of cleaning out the machinery and at the same time heating it to a point where a proper filling temperature may be had from the outset. At night, however, the clean-up should consist of first flushing with hot water and following with cold water until all equipment is cooled.

“Significant spoilage in both the first and second lots of samples indicates that there is a persistent source of contamination and the canner should make a detailed search for “pockets” in the equipment. If he cannot improve the situation by his own efforts, he should consult some qualified laboratory.

“Process. If unprocessed cans show little or no spoilage, this is not to be taken to mean that the process may be reduced with safety. A favorable condition at any part of the pack carries no insurance that this condition will be maintained throughout the pack. Where the condition of the unprocessed test cans is favorable, however, the canner may be satisfied that his process has provided a high factor of safety against spoilage.

“The following open bath processes are suggested for tomato juice. These processes should be adequate where precautions are taken to keep contamination at a low level.

Processes at 212°F.

Size of Can	Time at 212° F.
No. 1.....	15 minutes
202.....	20 minutes
No. 2.....	25 minutes
No. 10.....	40 minutes

“In the event of high spore contamination, these processes may not be adequate. There are no data upon which to base process suggestions that would apply to all con-

ditions of contamination. The initial temperature should be 170° to 180°F. To insure this temperature, the juice should be filled at about 190° F."

Stern, Hegarty, and Williams'¹⁴ Procedure for Isolating *Bacillus thermoacidurans* from Spoiled Tomato Juice. The laboratory technic involved in isolation of *Bacillus thermoacidurans* from spoiled tomato juice was studied by Stern, Hegarty, and Williams. The technic finally adopted was to open the can aseptically and to place one ml. of the juice in each of three sterile Petri dishes, pouring into each dish approximately 20 ml. of proteose peptone acid agar medium. After hardening, the plates should be incubated at 55°C. (131°F.) for 48 hours. Preliminary to this work organoleptic examinations should be made on the juice.

TOMATO PUREE (PULP)

This is prepared by concentrating tomato juice to a fraction of its original volume. This results in economy in shipping and storage. Arengo-Jones and Grant¹⁵ stated that a solid content of 22.5 per cent could be obtained without greatly influencing flavor or color. They also reported the rate of heat penetration into canned purée to be very low.

Tomato puree is packed in several sizes of cans, depending largely where the product is going to be used. It is filled into cans between temperatures of 76.6°C. (170°F.) and 82.2°C. (180°F.). If processed at all, it is done in boiling water. The larger cans are generally not processed. Enough heat is present in the product to sterilize them.

Characteristics of tomato purée (pulp) and various methods for examining it have been received by Bigelow, Smith, and Greenleaf.¹

TOMATO PULP

This is much like tomato juice, the main difference being consistency. This latter quality is secured by concentrating the juice in glass-lined tanks or similar containers. Effort is also made to preserve color and prepare a juice which will not settle. The manufacture of tomato pulp as well as methods of examining it have been reviewed well by Bigelow, Smith, and Greenleaf.¹

Catsup. This is probably the commonest tomato product; it has received considerable attention from those who are engaged in the enforcement of the Food and Drugs Act. The methods of manufacture are outside the scope of this book.

Catsup must be bottled hot if it is to keep. Much trouble results in the factory from careless and haphazard methods of temperature control. In these days of delicate control apparatus, there is no need to use obsolete methods, such as placing a thermometer in a few bottles to determine the temperature. Ayers and Osborne,¹⁶ prompted by fermentation and spoilage troubles in bottled catsup, used thermocouples for determining the temperatures in the bottles. Wide variations existed at different points within the container. The temperature in the center of the catsup was nearest the filling temperature; at other points it fell below the filling temperature. The differences in temperature of the contents of a given container varied with the temperature of the container when it was filled with hot catsup. In commercially filled catsup bottles the temperature on

15. Arengo-Jones and Grant. 1939. *The Canner*, October 21, 1939.

16. Ayers and Osborne. 1927. *Glass Container* 6, Nos. 3 and 4.

the inner surface of the cap never reaches a point high enough to have pasteurizing value. This is true regardless of whether the container is upright or on its side. A short heat treatment for hot filled bottled catsup after capping was effective in raising the temperature sufficiently to prevent spoilage. Catsup should be filled at temperatures above 77°C. (170°F.), capped, and processed for at least five minutes at 88°C. (190°F.).

Spoilage of Tomato Catsup. The chemical constitution of tomato catsup makes it susceptible to the attack of various microorganisms. Those which attack carbohydrates seem to be most important; at least the deteriorations in which sugar is attacked are most common. They result in both a change in state, owing usually to gas formation, and a change in flavor. "Black neck" in the bottle is a chemical decomposition resulting from formation of iron tanates.

Spoilage by Yeasts. Fermenting yeasts have caused much trouble in tomato products. Many of these cases have not been reported in the literature. A case of this type of spoilage was reported by Ayers.¹⁷ The bottles when opened showed considerable pressure and in one bottle it was over 30 pounds per square inch. When the bottles were opened the catsup was forced out quite violently in a manner well known to those who have examined spoiled foods in tin or glass containers. A yeast was isolated which could form gas in catsup of different brands. Ayers found that the yeast was not destroyed at a temperature of 60°C. (140°F.), for five minutes but was when heated 10 minutes, in tomato juice. Ayers called attention to the fact that the temperature of the catsup as it leaves the filling machines is not the true temperature after it is in the bottle. The final temperature is influenced by the temperature of the bottle. He gave the following data:

A 9½-ounce bottle which was at room temperature at about 24°C. (75°F.) was filled with tomato catsup at a temperature of 76.8°C. (170°F.). The temperature at the top of the bottle immediately after filling was only 68.3°C. (155°F.). Such data indicate that the bottles should be hot when filled. Ayers' experiments indicated that when the process of bottling hot without subsequent holding was depended on, a filling temperature as high as 82.2°C. (180°F.) would not stop yeast fermentation if the infection occurred at the time of bottling and if the bottles were at room temperature.

Spoilage of Catsup by Bacteria. Bacteria have also been incriminated in the spoilage of catsup. Mickle and Breed¹⁸ experienced difficulty at first in isolating viable bacteria from spoiled tomato catsup, but when fresh samples and proper media were used, colonies appeared on the plates. Tomato juice and tomato pulp broth were found to be most satisfactory. An organism, *Lactobacillus lycopersici*, was isolated and described. This organism had been encountered by many who had worked on tomato products spoilage. For instance, investigators at the Research Laboratory of the National Canners Association showed that spoilage in tomatoes was due to the survival of a non-sporulating organism which may be repeatedly recovered from swelled canned tomatoes. While the organism does not form spores, it is sufficiently heat resistant to survive some processes. Esty stated that the organism was distributed throughout sections in which tomatoes are raised and also in and about factories which have been packing tomato products. It was further stated that the presence of this non-sporulating organism in canned tomatoes was not always proof that it could survive sterilization applied to the cans. Defective cans were suggested as one method by which the organism could get into the can. Esty also stated that the presence of yeasts in canned tomatoes probably indicated a defective container. *Lactobacillus lycopersici* is much like *Bacillus pleofructi*. However, Mickle and Breed believed they were sufficiently different to justify a new name for the organism which they isolated from catsup. They discussed the organisms as follows:

17. Ayers. 1926. Glass Container 5, No. 4.

18. Mickle and Breed. 1925. N. Y. Agr. Expt. Sta., Tech. Bull. 110.

“However, the typical strains of *B. pleofructi* isolated from fruit juices were pleomorphic, showing as coccobacilli in broth and agar cultures and as long slender rods in fruit juices. They were also distinctly capsulated. Thirteen of the sixteen cultures produced acid in litmus milk, ten of them sufficient to curdle. Three aberrant strains resemble *L. lycopersici* more closely in that they produced no change in litmus milk.

“The two organisms resemble each other in showing the general characters of lactobacilli. They differ from the usual lactobacilli in that they produce gas abundantly under proper conditions. They are alike in that they produce this gas most abundantly in the fruit juices from which they are isolated, while they ordinarily fail to produce gas in sugar broths.”

This microorganism was observed by Esty¹⁹ of the National Canners Association.

Lactobacillus lycopersici was also described later by Pederson²⁰ who studied 11 strains besides the original one isolated by Mickle and Breed. Pederson described six other bacteria as agents in the spoilage of tomato produces as follows:

Lactobacillus lycopersici, *Lactobacillus gayoni*, *Lactobacillus pentoaceticus*,
Lactobacillus mannitopoeum, *Lactobacillus plantarum*, *Leuconostoc pleofructi*.

They are completely described in Pederson's original paper. None of the species were resistant to heat and should, therefore, be easily killed when proper methods of manufacture are used. Pederson devised a key for identification of these organisms without a study of all characteristics.

Windred²¹ mentioned an organism from tomato pulp which caused sliminess. It resembled *Bacillus ruminatus* Gottheil.

Gaseous spoilage of tomato products was also studied by Jones.²² The organisms found to be responsible were Lactobacilli in all cases; three species were found—*Lactobacillus gayoni*, *Lactobacillus lycopersici*, and a species closely related to the latter. These organisms were found to be readily killed by heat, one minute at 75°C. (167°F.) being sufficient even when they were growing in concentrated tomato pulp. Jones, therefore, pointed out the necessity of using clean methods of manufacture.

Preservation of Catsup. The various substances added to catsup have been studied to determine whether they might have bactericidal properties as well as flavoring properties. At other places in this book, the agents discussed below are discussed in other relations. Probably no one substance will function as a preservative alone.

Salt. Salt is added to catsup to improve the flavor. Bitting²³ tested its effect on preservation. He added 5, 10, 15, 20, 25, and 30 grams of salt to 100 ml. portions of catsup which were then inoculated with mold. Five grams of salt seemed to have no effect. In the culture containing 10 grams growth appeared as quickly as it did in the control, but was not as extensive. In the 15-gram solution or culture, growth was retarded for four days. With the 20-gram culture, growth was five days slower than the normal; after that, there was only slight development. The results with the 25-gram culture were not materially different from those with the 20-gram culture. No development occurred in the 30-gram culture.

Bitting also made inoculations with a yeast. The 5-gram culture caused slight inhibition while the 10-gram solution allowed a thin film to form in two days, which ordinarily developed as a rather thick film in 24 hours. No development of the yeast took place in the 15-gram salt medium.

Analyses of 18 brands of catsup by Pederson and Breed²⁴ showed a salt content which varied from 1.6 to 3.7 per cent.

Sugar. Bitting tested the effect of sugar on both the mold and yeast in tomato bouillon. No effect was noticeable until the concentration of sugar had reached 25 grams per 100 ml. In this concentration growth appeared as readily as in the lower concentrations but was less abundant. In the 25- to 40-gram concentrations there was less development as the amount of sugar was increased. In the 70- and 75-gram media, growth was delayed one day. In the 80-, 85-, and 90-gram media, growth was delayed two days. Bitting prepared heavier solutions. When the concentration reached 170, 180, 190, and 200 grams, development of molds was very slow.

The yeast could not develop in concentrations above 80 grams per 100 ml. Pederson and Breed²⁴ found sugar to be ineffective as a preservative in catsup. Even 35-per cent concentrations inhibited certain types only. Combinations of sugar and salt proved effective; 15 per cent of sugar and 3.5 per cent of salt stopped growth of all organisms used except the yeast. According to Pederson and Breed, the sugar content of 18 brands of catsup varied between 15 and 26.3 per cent.

Spices. These are added to catsup mainly to improve the flavor. However, some of them possess bactericidal properties. Bitting²³ investigated this property in tomato bouillon using water infusions, acetic acid extracts, and oil extracts of spices. Bitting's experiments with water extracts showed that cinnamon and cloves were the strongest antiseptics. These checked growth when used in small amounts; three ml. of the cinnamon extract and one ml. of the clove extract were required to inhibit the growth of the mold. Mustard, paprika, and cayenne pepper also inhibited growth but five ml., the highest concentration used, did not stop growth. Ginger, mace, and black pepper had no effect. Bitting secured slightly different results with the yeast. Cinnamon showed the strongest action; cloves came next. After these came cayenne and black pepper. Ginger, mustard, and mace had no effect.

Since acetic acid extracts of spices are frequently used in catsup, Bitting used such extracts of allspice, celery, cloves, coriander, garlic, and black pepper. These extracts were added to tomato bouillon; one set of tubes was inoculated with the mold and the other with the yeast. No growth of mold occurred with allspice and cloves; the celery extract checked growth considerably. Coriander and garlic were not very active. The yeast seemed to be just a little more resistant. The oil extracts were also tried, but were believed to be unsuitable since too large an amount would have to be used. The delicate tomato flavor was interfered with.

Vinegar and Acetic Acid. According to experiments by Bitting, 30 per cent of 50-grain distilled vinegar added to tomato bouillon checked the growth of mold. As the concentration increased, the extent of inhibition was also increased. Acetic acid was much more active. One-half of one per cent gave about the same inhibition as 30 per cent of vinegar.

24. Pederson and Breed. 1926. N. Y. Agr. Expt. Sta. Bull. 538.

Sodium Benzoate. This compound is permitted as a preservative in catsup. In 1909 Bitting studied its preservative ability in tomato bouillon inoculated with a yeast and a mold. Tomato gelatin was prepared with .1, .5, 1, and 2 per cent of sodium benzoate. There was no development of the mold in the presence of 1 and 2 per cent of benzoate; in the presence of .5 per cent, growth was retarded, but normal in the presence of .1 per cent. Experiments with catsup containing 1/16, 1/12, and 1/10 of 1 per cent were also made. These concentrations checked growth of the mold and even caused distortion of the filaments of the mold. Irregular results were secured as far as complete inhibition of growth was concerned. Bitting was led to conclude that sodium benzoate gave uncertain results as a preservative. Pederson and Breed²⁴ reported that .2 per cent of sodium benzoate was required to stop the growth of all bacteria used in their studies. However, certain types were less resistant. A yeast isolated by Ayers was quite resistant. Tanner and Strauch²⁵ previously reported that yeasts were quite resistant to sodium benzoate.

Effect of Combinations of Ingredients as Preservatives in Catsup. Pederson and Breed²⁴ studied this problem and suggested a number of formulas. They discussed the matter as follows:

Combinations of sugar and salt were found to be much more effective in preventing spoilage than a combination of either one with acid. In fact, with the addition of 25 per cent of sugar to the medium, the acid required to stop growth of the organism could be lowered only about .1 per cent. Four per cent of salt had no more effect than the sugar in lowering the quantity of acid required. On the other hand, 10 per cent of sugar and 3.5 per cent of salt inhibited growth of the majority of organisms, while 15 per cent of sugar and 3.5 per cent of salt inhibited growth of all except the one resistant yeast. The addition of a small quantity of acetic acid, that is, from .3 to .4 per cent, lowered these figures but slightly. Combinations of 15 per cent of sugar, 3 per cent of salt, and .3 per cent of acid; of 15 per cent of sugar, 2.9 per cent salt, and .4 per cent acid; or of 10 per cent sugar, 3.5 per cent salt, and .4 per cent acid were all found to be effective in preventing growth of the bacteria.

HOWARD AND STEPHENSON'S METHOD FOR MICROANALYSIS OF TOMATO PRODUCTS

The original statement of this procedure by Howard²⁶ and by Howard and Stephenson²⁷ has been modified several times. Much has been written for and against the method. It may leave much to be desired when compared with other methods of analysis, but when the procedure for arriving at the technic is studied, its merit is also obvious. The method has played an important role in raising the standard of tomato products and forcing out of business those manufacturers who were unwilling to use the best methods of manufacture.

This method for the examination of catsup which has been in use since 1911,²⁸ probably because no one has proposed a better one to replace it, is based on examination of tomato products for yeasts, molds, and bacteria, and it is thus assumed that

25. Tanner and Strauch. 1926. Soc. Expt. Biol. and Med. Proc. 23, 449.

such microorganisms indicate decayed fruit was used or the method of manufacture is faulty. This latter possibility was found to be the case in an instance quoted by Howard and Stephenson. A manufacturer was using ripe, fresh tomatoes and still secured high counts of microorganisms in the final product. They resulted from faulty methods in the factory and not from the presence of rot in the tomatoes. The method may thus serve the manufacturer as well as the consumer.

Association of Official Agricultural Chemists' ²⁸ Procedure for the Howard-Stephenson Method. The section numbers in the procedure are those in the original publication.

APPARATUS

(a) *Compound microscope*.—Equipped with good objectives and oculars, giving magnifications of approximately 90, 180, and 500 diameters. For convenience of use the lenses should be adjusted so as to be parfocal. A mechanical stage is highly desirable. It is essential that the combination giving the low magnification be capable of adjustment to give an area of the field of view of 1.5 sq. mm. (a circle whose diameter is 1.382 mm.). With the higher powers the working distances must be ample to allow the free use of the blood-counting cell.

(Courtesy Bausch and Lomb Optical Co.)

FIG. 3. Side View of the Cell.

The flat circular area A, the contact areas B, and the 33 x 33 mm. cover glass, are optically worked. These areas should be thoroughly cleaned before using the cell. Cotton batting dipped in strong hydrochloric acid is used in cleaning the surfaces. Rinse thoroughly with distilled water, then with alcohol, and finally with acetone. All particles of lint or dust must be removed with a camel-hair brush.

Place a drop of the fluid to be tested on the circular disc A. Spread it evenly over the disc in order to avoid squeezing out the more liquid parts around the edge of the disc. Rest the cover glass against the edge of one of the contact areas B, and tilt it gently down onto the liquid. It is important to note that no liquid should be allowed to penetrate between the contact areas and the cover glass, since this would interfere with the proper contact between these surfaces. The use of too much fluid is to be avoided for this reason.

The cell has been constructed to give a depth of 0.1 mm. of fluid when the cover glass is in sufficiently close contact with the areas B so that Newton's rings may be observed. The rings appear between the surfaces in contact. These colored bands, or rings, are accurate criteria of the proper contact. Inability to obtain them is an indication of insufficient cleaning of the contact surfaces.

In making a mold count it is necessary to have a field of 1.5 sq. mm. area, that is the diameter of the field should be 1.382 mm. This may be obtained by using a 16 mm. objective and a 10× eyepiece, adjusting the draw-tube length to give the correct field size. For ready calibration a circle 1.382 mm. outside diameter is etched on the right hand rail. Using the objective and eyepiece mentioned the microscope is focused on the etched circle. The draw tube is then adjusted until the circumference of the microscope field coincides with the *outside* of the circle.

(b) *Drop-in cross-ruled disk*.—For estimating lengths of mold filaments, an ocular drop-in disk cross-ruled in sixths of the ocular diaphragm opening is desirable.

(c) *Blood counting cell*.—Preferably ruled in the Thoma or the old Neubauer system of rulings. The so-called "improved" system of Neubauer may be used if the depth of the chamber is 1/10 mm. and care is taken to select the proper sized area for counting.

(d) *Howard mold-counting cell*.—Constructed like a blood-counting cell but with unruled central disk about 19 mm. in diameter.

28. Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists, Fifth edition, 1940.

29. Bonney. 1942. Assoc. Off. Agr. Chem. J. 25, 464-465.

In making mold counts of tomato juice, catsup, and puree, use the product as is, but with tomato pastes mix first with H_2O so that the tomato solids will give a sp. gr. of 1.035. If the paste contains salt or other substance that influences the sp. gr. materially, take this into consideration in making the dilution.

Clean the special Howard cell so that Newton's rings³⁰ are produced between the slide and the cover glass. Remove the cover and place a small drop of the well-mixed sample upon the central disk; using a knife blade or scalpel, spread the drop evenly over the disk, and cover with the glass so as to give an even spread to the material.

It is of the utmost importance that the drop be taken from a thoroly mixed sample and spread evenly over the slide disk. Otherwise, when the cover slip is put in place the insoluble material, and consequently the molds, may be more abundant at the center of the mount. Avoid using a drop that is much greater than is sufficient to fill the space between the center disk and cover slip. Discard any mount showing uneven distribution, absence of Newton's rings, or liquid that has been drawn across the moat and under the cover glass.

Place the slide under the microscope and examine with such adjustment that each field of view covers 1.5 sq. mm. This area, which is of vital importance, may frequently be obtained by adjusting the draw-tube in such a way that the diameter of the field becomes 1.382 mm. Where such adjustment by means of the draw-tube is not possible, it is sometimes necessary to have a mechanic make an accessory drop-in ocular diaphragm with the aperture accurately cut to the necessary size. The diameter of the area of the field of view can be determined by use of a stage micrometer, or by employing the rulings on the blood-counting cell. In order to use the latter method it is necessary to bear in mind that a square whose diagonal is 1.382 mm. has sides of approximately .977 mm. Hence the mm. scale on the blood-counting cell can be used by such adjustment that the circle of the field of view cuts off the necessary amount from each corner of the mm.-ruled square. When the instrument is properly adjusted, the quantity of liquid examined per field is .15 c.mm. (.00015 cc.).

Examine at least 25 fields from each of two or more mounts taken in such manner as to be representative of all sections of the mount. Observe each field, noting the presence or absence of mold filaments and recording the result as positive or as negative, as the case may be. No field should be considered positive unless the aggregate length of not more than three of the filaments present exceeds approximately $\frac{1}{6}$ of the diameter of the field. Calculate the proportion of positive fields from the results of the examination of all the observed fields and report as percentage of fields containing mold filaments.

Realizing the necessity of some study of tomato histology, Howard prepared "Outlines For Instruction in Tomato Microscopical Methods" in which much preliminary work is outlined. Accuracy in using the Howard method for tomato products requires some experience on known samples as well as rigorous attention to details. Here are some of the factors which must be closely attended.

Standardization of Microscope Field. The microscope field must be carefully standardized to an area of 1.5 square millimeters. To meet this requirement, the field must have a diameter of 1.382 mm. The best method to accomplish this is probably with a stage-micrometer. While applying the Howard count for molds and yeasts and spores

30. These are rainbow colored rings produced at the point of contact when polished plates of glass are pressed against each other. In a letter to the author Dr. Howard commented as follows about Newton's rings: "In talking with various users of the method, and observing others in its employment, I find that some are not as careful, in obtaining the Newton's rings as they should be . . ."

31. Since difficulties were anticipated in securing blood-counting cells with the old Neubauer ruling, Bonney²⁹ proposed substitution of this last paragraph under procedures for counting "Yeasts and Spores" and "Bacteria" by the Howard method for the description of technic as previously given.⁴⁷

to frozen fruit products, Needham and Fellers³² used a compound binocular microscope and found many advantages. Since a field 1.382 mm. in diameter is specified, it was found that a Bausch and Lomb binocular microscope of 163 mm. tube length with a 10× ocular, a 16 mm. objective, gave a field 1.422 mm. in diameter. The error in the diameter of the field is less than three per cent.

Mounting Specimens on the Mold-Counting Chamber. Clean and polish both the chamber and cover glass until a good display of Newton's rings is obtained when they are in contact.

The great dependence on an arbitrary procedure for the control of tomato products and the differences in results which are obtained with even slight modifications in technic has been shown by Howard.³³ The standard procedure as stated by Howard reads: "Remove the cover and place by means of a knife blade or scalpel, a small drop of the sample on the central disk." In order to determine whether the instrument used to place the drop of sample on the disk had any influence on the results, Howard used various ones, such as a large scalpel, a medium scalpel, a platinum loop, a pipette, and a forefinger of the operator. Such a series of examinations was made by three microscopists. The results indicated that a considerable percentual variation occurred with the methods of working used. It was stated that the pipette method of delivering a drop of sample to the slide was not satisfactory. Medium and large scalpels were most satisfactory in that the smallest variations in mold counts were secured when these were used.

Clean the slide and *spread* the drop over the disc as evenly as possible with the point of the scalpel before putting the cover glass into position, which, in this case, should be done quickly. Make sure that Newton's rings are present. If the specimen thus mounted does not seem to the naked eye to be uniform but has streaks or uneven patches in it, this condition, if slight, can sometimes be overcome by tapping the center of the cover two or three times gently with a pencil point or the wooden top of the scalpel handle. This tapping operation should not be extensive or the consistency of the entire sample will be changed; much of the cellular fibrous material will work out toward the edge, leaving only the fine granular and liquid portion of the main part of the disc. Test this by tapping the cover glass 30 to 40 times and compare the resulting mount with one properly made. The effect of tapping varies greatly with the thickness of cover glass used. Cover glasses are made in several different thicknesses, of which the following seem most common: 1 mm., .6 mm., and .4 mm. Although the thick form is not as easily broken as the others, the medium one is preferable for general routine work. A properly mounted specimen should be practically free from air bubbles.

The size of the drop should be so taken that when the cover slip is in place the disc will be just about covered by the specimen without any very appreciable proportion having been squeezed out into the moat surrounding the disc. No mount is proper for use if Newton's rings are not visible when the mounting is completed.

Howard³³ suggested the use of the net micrometer for making mold counts. This was considered desirable for the instructions that no field should be considered positive unless the aggregate length of the filaments present exceeds approximately one-sixth of the diameter of the field, left too much to the analyst. Two of Howard's colleagues, Stephenson and Makenison, suggested having the mold counting chamber ruled in squares of .23 mm. on a side ($1/6$ of 1.382 mm., the diameter of the field in view).

32. Needham and Fellers. 1924. Science 59, 341.

33. Howard. 1922. Assoc. Off. Agr. Chem. J. 6, 50-51.

Mold filament counting usually seems obscure to the novice. This situation clears considerably with instruction by competent mold counters and experience. Risk of loss by seizure of the product should indicate the desirability of using only trained counters. Various structures in the tomato and mold filaments have similar appearances and it is not easy for an inexperienced microscopist to distinguish them. Haynes³⁴ mentioned the following six characters which help to distinguish mold filaments from tomato filaments:

1. *Segmentation*: Some mold filaments are segmented. Tomato filaments are never segmented.

2. *Granulation*: Mold filaments are granular. Tomato filaments are clear, vitreous, or fibrous.

3. *Parallelism of the Sides of the Cell Wall*: The sides of the cell walls are always parallel in mold hyphae. In tomato filaments the sides of the filament often appear constricted or expanded.

4. *Comparison of Focal Plane or Side Walls*: The two side walls of mold hyphae are always in focus at the same level while the side walls of other filaments may come into focus at two different levels. This results from the fact that hyphae are cylindrical or tubular filaments while the tomato filaments are ribbon-like.

5. *Character of Branching*: Branching occurs at sharp angles among mold hyphae while it may be rather indefinite among other filaments.

6. *Appearance of Ends of Filaments*: The ends of mold hyphae are blunt, never flared or pointed as they may be on tomato filaments.

29

YEASTS AND SPORES

Fill a graduated cylinder with H₂O to the 20 ml. mark and add the sample till the level of the mixture reaches the 30 ml. mark. Close the graduate, or pour the contents into an Erlenmeyer flask, and shake vigorously for 15-20 seconds. To assure thoroughness the mixture should not fill more than $\frac{3}{4}$ of the container in which the shaking is performed. For tomato sauce or pastes, or products running high in the number of organisms or of heavy consistency, use 80 ml. of H₂O with 10 ml. or 10 g. of the sample. In the case of exceptionally thick or dry pastes, it may be necessary to make an even greater dilution.

Pour the mixture into a beaker. Thoroughly clean the counting cell so as to give good Newton's rings. Stir thoroughly the contents of the beaker with a scalpel or knife blade and after allowing to stand 3-5 seconds remove a small drop, place it upon the center disk of the blood-counting cell, and cover immediately with the cover glass, observing precautions to secure production of Newton's rings and avoiding the overflowing of the liquid so as to run in between the cover and supporting surfaces of the slide. Allow the slide to stand not less than 10 min. before beginning to make the count. It is customary to make the count with a magnification of about 180 to 220 diameters.

If a counting cell³¹ ruled by the Thoma or old Neubauer system is used, count number of yeast and mold spores on one-half of ruled squares on disk (this amounts to counting the total number in 8 of the blocks, each of which contains 25 of the small ruled squares, or a total area examined of .50 sq. mm.). (If a counting cell having a depth of chamber of 1/10 mm. but ruled by some other system is used, care must be taken that the total area examined is .50 mm.) Total number thus obtained equals number of organisms in 1/60 c.mm. (1/60,000 ml. of original product) if a dilution of 1 part of sample with 2 parts of water is used. If a dilution of 1 part of sample with 8 parts of water is used, multiply the number by 3. In making the counts, the analyst should avoid counting twice the organisms that rest on a boundary line between two adjacent squares.

34. Haynes. 1941. *Canning Age*, August 1941, 438-439; 458.

Determine the number of rod-shaped bacteria from the mounted sample used in 28, but before examination allow the sample to stand not less than 15 min. after mounting. Use a magnification of about 500 diameters.

If a counting cell³¹ ruled by the Thoma or old Neubauer system is used, count and record number of bacteria having a length greater than $1\frac{1}{2}$ times their width, in an area including 5 of the small squares. Count number in 5 such areas, preferably 1 from near each corner of ruled portion of slide and 1 from near the center. Since each of these groups has an area of .0125 sq. mm. the total area examined is .0625 sq. mm. (If a counting cell having a depth of chamber $\frac{1}{10}$ mm. but ruled by some other system is used, five .0125 sq. mm. areas from different parts of the slide should be examined so that the total area counted covers .0625 sq. mm.) Determine total number of rod-shaped bacteria in the .0625 sq. mm. area examined and multiply by 480,000. This gives the number of this type of bacteria per ml. If a dilution of 1 part of sample with 8 parts of water, instead of 1 part of sample with 2 parts water, is used in making up the sample, then total count obtained must be multiplied by 1,440,000. The bacteria sometimes exhibit slight motion and thus may present

FIG. 4. Showing Thoma and Improved Neubauer Hemacytometer Rulings.

A. Thoma. One sq. millimeter divided by lines into twenty spaces in each direction, each space equalling $\frac{1}{20}$ sq. mm. To facilitate counting every fifth space is subdivided by a line through the middle. (After Howard and Stephenson, 1917.)

B. Neubauer. The improved Neubauer ruling has been recently introduced. The square millimeter in the center is divided into 25 squares each in turn being subdivided into 16 squares of $\frac{1}{400}$ square millimeter area. There are, therefore, 400 of these small divisions in the center, grouped into 25 units of 16 smaller squares. This subdivision is accomplished by a "split" fifth line which appears through the microscope as a distinct but transparent boundary for each of the 16 smaller squares.

momentarily an end view instead of a side view. For this reason it is necessary to keep them under observation long enough to establish their true character. Thus far it has proved impracticable to count the micrococci present as they are likely to be confused with other bodies frequently present in such products. See page 678 for explanation of calculations.)

The above is a complete statement of the Howard-Stephenson method. During the many years that it has been used, various suggestions have been made to make it easier to use. Some of these are discussed below.

Explanation of Calculations. Fig. 4 has been prepared to make somewhat clearer the explanation of the areas denoting the yeast and spore and bacterial counts. The

light lines in the figure show the arrangement of rulings on the entire slide. The squares (*A, A, etc.*), and rectangles (*B, B, etc.*) designated in the figure by the heavy lines indicate the portions used for the yeast and spore and for the bacterial counts, respectively. The eight large equares, *A, A, etc.*, are the squares used for yeast and spore counts. Each of these squares has 25 of the small squares. The sum of organisms counted in the eight squares marked *A, A, etc.*, is the number in 1/60 c.mm. if a dilution of one part of product to two parts of water is used.

Yeast and Spore Count. The ruled square on the slide is 1 mm. on each side and the cell is 1/10 mm. deep. The volume of the ruled part is therefore 1/10 c.mm. The ruled area is divided into 16 large squares and the number of organisms is counted in eight of these, which is equivalent to 1/2 of 1/10 c.mm., or 1/10 c.mm. If a dilution of one part of the product to two parts of water is used 1/1 of 1/20 c.mm., or 1/60 c.mm. as representing the actual amount of original stock in which organisms are counted, is obtained.

Bacterial Count. The rectangles, *B, B, etc.*, each including five of the smallest squares, represent the areas used in making the bacterial count. Similar rectangles of equal area might be selected, the object being to count five such areas well distributed over the ruled portion of the slide. The *average* number of bacteria counted on five rectangles, such as *B, B, etc.*, multiplied by 2.4 million, equals the number of bacteria per milliliter. In calculating the bacteria, it is observed that there are 400 (20×20) small squares on the slide. The numbers of bacteria in rectangles (*B, B, etc.*), each containing five of these small squares, are counted and an average made. This average represents the bacteria in 1/80 of the total ruled area. Since the cell is 1/10 mm. deep, the volume represented by the organisms counted is $1/80 \times 1/10$ or 1/800 c.mm. With the usual dilution of one part of product to two parts of water the actual volume in which the number of organisms is determined is 1/3 of 1/800 cm. or 1/2400 c.mm. or 1/2,400,000 ml.

Vincent's Method for Examination of Tomato Paste. Vincent³⁵ has attempted to overcome the errors of the Howard method by adapting the Breed smear to tomato products. The method is described as follows: "The catsup is diluted with two parts of sterile water, since this dilution has proven satisfactory in counting most specimens when the Zeiss counting chamber is used. With a sterile pipette calibrated to deliver .01 ml. the diluted catsup is deposited on a second glass slide and evenly spread over an area of 1 sq. cm. by means of a sterile needle. After drying, the slide is immersed in 95 per cent alcohol for one minute to fix the smear, dried in air, stained with Loeffler's methylene blue for two minutes, washed in water, dried and examined with the 1/12 in. oil immersion lens." The rest of the procedure is identical with that outlined under Breed's microscopic method for counting bacteria in milk. The microscope is standardized to bring the diameter of the field to .205 mm. Thirty fields are counted and the average for one field is multiplied by three on account of the dilution of the catsup. This result is then multiplied by 300,000, which represents the number of bacteria per milliliter.

Vincent compared this microscopic count with the count secured with the Zeiss blood counter. The latter count was always much smaller than the former. Vincent believed that the cocci should be counted since they probably take as important a part in the spoilage of tomatoes as the rods.

This method has not received official recognition.

Bertarelli and Marchelli's³⁶ Method for Controlling Tomato Products. These two Italian investigators made a comparative study of the Howard and Vincent methods for the control of tomato products. They believed the Vincent method to be superior although both methods were open to considerable error. They proposed the following method:

Two milliliters of the product are made up to 50 ml. with distilled water, shaken thoroughly, and filtered through four thicknesses of muslin. The residue is carefully washed with another 50-ml. portion of distilled water and the filtrate collected in the

35. Vincent. 1918. *J. Bact.*, 3, 183-185.

36. Bertarelli and Marchelli. 1920. *Ann. d'Ig.* 30, 309-322.

beaker containing the original filtrate. The combined filtrate is estimated to contain all but about 20 per cent of the bacteria originally present and in estimating the bacterial count a correction is made for this. By careful manipulation, 1/200 ml. portions are dropped from a pipette on glass slides, spread over the surface with a platinum wire, fixed with alcohol-ether, stained with Loeffler's methylene blue, and subjected to microscopic count in the usual manner.

Miller's³⁷ Modification of the Howard and Stephenson Technic. Another modification of the Howard and Stephenson technic was suggested by Miller. He suggested preliminary heating of the material (20 ml. of tomato juice or 5 ml. of paste diluted to 30 ml.) successively with from 2 to 4 ml. of Loeffler's alkaline methylene blue and 2 ml. of Ziehl-Neilsen's carbol-fuchsin. After reducing any excess of stain with 5 to 10 drops of formaldehyde the material is diluted with 60 to 120 ml. of water and shaken well. It is then used for preparation of slides according to the usual technic. Artificial light should be used for the examination of the slides.

Smith's³⁸ Methods for Detection of Mold in Various Products to Which Tomato Sauce Has Been Added. These methods were devised for detecting presence of mold filaments in several products to which tomato sauce has been added. Owing to the fact that the technic differs for the various products, Smith gave the procedure for the following three groups. Since different samples of products within the same group vary in consistency, the analyst's ingenuity must be used when applying the method to certain samples.

TOMATO SOUP WITH OR WITHOUT CREAM

The chief difficulty with examination of this product is the large amount of starchy material, such as cracker crumbs and flour, which may be present. In the case of heavy soups, it is best to place the can in hot water for several minutes until thoroughly warmed. This facilitates stirring and measuring the soup. With thinner products this preliminary heating is unnecessary. Place 10 ml. of thoroughly mixed soup in a large centrifuge tube, 50 ml. or larger is best, and add three ml. of a concentrated solution of potassium hydroxide—a little more will do no harm. (If desired, from 10 to 15 ml. of methyl ethyl ketone may be added at this point to remove the fat. After stirring thoroughly, the ketone, which rises to the top and is stained red, is poured off. Since the potassium hydroxide saponifies the fat, the ketone is usually unnecessary.) Stir for a few minutes until the starch in the soup has been dissolved and the tissues cleared. Now add sufficient water to fill the tube and centrifuge. In heavy soups the gelatinizing of so much starch sometimes interferes with the proper settling of the solids during centrifuging. If the liquid remains cloudy it may be necessary to discard the sample and start again with only five ml. of soup and proceed as usual with the usual three ml. of potassium hydroxide. When the supernatant liquid is clear and the solid particles have settled out, the liquid should be poured off and examined for mold fragments. If no mold filaments are found in the supernatant liquid, add enough water to the residue in the centrifuge tube to bring it to the original volume of soup, mix, and count by the usual Howard technic. If desired, a few drops of gentian violet may be added. This stains the mold filaments and facilitates counting.

Since the KOH has been found in time to etch the mold-counting slide and cover glass, it is best, if much mold counting is to be done, to neutralize the alkali with a few drops of 50 per cent phosphoric acid. This is done after the supernatant liquid is discarded and before the water is added to bring the volume up to the original 10 ml.

PORK AND BEANS, SPAGHETTI WITH TOMATO SAUCE, SPAGHETTI WITH MEAT BALLS OR MEAT, RAVIOLI, CHILI CON CARNE, AND TAMALES

All of these products are treated essentially the same. The unopened can is placed in hot water and heated until the contents are thoroughly warmed. This preliminary heating thins the tomato sauce so that it will separate more readily from the solid portions of the product. The can is then opened and the contents dumped into a rather

37. Miller. 1920. *J. Ind. Eng. Chem.*, 12, 766-769.

38. Smith. 1940. Personal communication from Dr. B. J. Howard.

coarse sieve, a six-mesh one has been found satisfactory. With some products the sauce runs through at once, but in the case of some beans and spaghetti it may take 10 or more minutes. It should drain at least until a major portion of the liquid part has been drained through. Mix the sauce thoroughly, place 10 ml. in a centrifuge tube, and proceed as for tomato soup. In counting products containing meat care should be used not to confuse mold filaments and muscle fibers which bear a superficial resemblance to each other although the muscle fibers are usually much thicker and the striations are often visible.

SARDINES OR OTHER FISH WITH TOMATO SAUCE

This product presents difficulty owing to the large amount of fat or oil. Since the sauce as made apparently contains little added oil, that found present in the finished product comes from the fish themselves. For this reason it is possible to discard the oil without removing any of the constituents of the original sauce. The can is heated in boiling water and the sauce drained off as in other products. The sauce is then thoroughly mixed and a portion placed in a centrifuge tube. This is centrifuged until the oil rises to the surface. The oil is discarded and 10 ml. of the remaining sauce is treated with three ml. of KOH just as in the other products. With herring tidbits or other products when there is but little oil, it is not necessary to remove it. Care should be used in the examination to differentiate between mold filaments and muscle fibers from the fish.

United States Department of Agriculture Standards for the Howard Method. The Government officials first stated standards for the Howard procedure³⁹ as follows: Not more than

Molds in 25 per cent of the microscopic fields.

Yeasts and spores—25 in 1/60 milliliter.

Bacteria—25 million per milliliter.

In 1916, the Bureau of Chemistry became a little more lenient and stated that there would be no condemnation unless the following were exceeded:

Molds in 66 per cent of the microscopic fields.

Yeasts and spores—125 in 1/60 milliliter.

Bacteria—100 million per milliliter.

On May 14, 1931, the Food and Drug Administration stated that the mold standard of 1916 was unjustifiably liberal. They stated that proceedings would be recommended against tomato products if mold filaments were present in more than 50 per cent of the microscopic fields. Government food-control officials believed that this new standard was a just one in view of the great improvements which had been made in the tomato-products industries. On July 27, 1938, it was announced in connection with tomato juice that pending consideration of a further lowering tomato juice would be regarded as adulterated when mold filaments are present in more than 25 per cent of the fields. Since these announcements material improvements have been effected by the industry. In the light of these advances, these mold-count limits are now unjustifiably liberal.

During the 1940 packing season, and pending consideration of further reductions after this season, actions under the Act will be instituted against tomato catsup, puree, and paste if mold filaments are present in more than 40 per cent of the microscopic fields, and in the case of tomato juice if

39. Howard. 1912. U. S. Dept. Agr.. Yearbook for 1911, 297-308.

mold filaments are present in more than 15 per cent of the microscopic fields.

Comminuted tomato products are often used in the fabrication of other food products, such as tomato soup, beans with pork, spaghetti sauce, etc. The use of comminuted tomato products with mold counts in excess of the above limits in the manufacture of other foods constitutes adulteration. Action has been and will continue to be taken against foods in which illegal comminuted tomato products have been used. Soon after promulgation of this standard, the Food and Drug Administration was petitioned to raise the tolerance from 15 per cent to 20 per cent of microscopic fields. The Administration appraised the situation and concluded that in the case of tomato catsup, purée, and paste, it was not unreasonable to expect canners to meet the mold tolerance of 40 per cent of microscopic fields announced in 1940. In the case of tomato juice, the tolerance was placed at 20 per cent of microscopic fields. Adequate allowances were to be made in applying the tomato-juice tolerance to those articles which have been homogenized. Comminuted tomato-juice products exceeding these mold-count tolerances cannot be used as ingredients of manufactured foods such as tomato soup, spaghetti sauce, etc., since this would constitute adulteration.

The Howard method has been criticized from many sides. It has inherent weaknesses, but they do not seriously invalidate the method. It has been stated that the method has been responsible for distinct improvement in quality of certain tomato products. It has enjoyed the approval of many of the largest manufacturers who have been interested in a high-grade product. A few of the criticisms may now be presented.

Prescott, Burrage, and Philbrick⁴⁰ condemned Howard's method of enumerating mold hyphae, yeast cells, mold spores, and rod-shaped bacteria in tomato products. Among the various sources of error were mentioned the low magnification used on unstained preparations making it almost impossible for the analyst to differentiate between particles of plant tissue and the desired microorganisms. These authors mentioned the fact that no attention was given to the coccus types which may be important in the spoilage of tomato products. Prescott and his colleagues also mentioned the indefinite directions which were often given. Bitting and Bitting,⁴¹ in a little monograph entitled "Ketchup," gave many objections to the Howard method of controlling tomato products. Some of these may be enumerated as follows: (See also Darling.⁴²)

1. Too indefinite directions concerning the putting of material into the counting chamber, the amount of shaking, the cleanliness of apparatus, sterility of apparatus, etc.
2. The use of different units of volume for reporting results.
3. Impossibility of differentiating between bacteria and bits of debris.
4. Arbitrary selection of rod bacteria for counting since cocci may be confused with other bits of material.
5. Yeasts and spores are counted together. They cannot be separated from each other nor from many other particles.

40. Prescott, Burrage, and Philbrick. 1917. *Abs. Bact.*, 1, 51.

41. Bitting and Bitting. 1925. *Ketchup*. Pub. by authors, Lafayette, Ind.

42. Darling. 1922. *N. Y. Agr. Expt. Sta. Bull.* 91.

6. In counting mold hyphae no distinction is made between large masses in the field and one thread.

7. No real relation exists between the organisms counted and the decomposition, for mere numbers of organisms are not always coincident with putrefactive activity.

Bitting and Bitting also pointed out that certain steps in the process of manufacture might influence the number of organisms which may be counted. A pulp may vary from an unevaporated tomato juice to a concentration which is represented by an evaporation of a volume of water up to 60 per cent and catsup may vary from a watery consistency to one which will scarcely flow from the bottle. They stated that a method which did not take into consideration the concentration would be deficient for judging the quality of a food. For example, a tomato juice with 10,000,000 bacteria per milliliter when evaporated to one-half its volume might have more than twice that number. A thin pulp with 10,000,000 bacteria per milliliter might easily be worse than a heavier one with 30,000,000 or 40,000,000 cells. These authors stated that it would, therefore, be impossible to concentrate any pulp to the consistency of a paste and have it pass the standards. Vincent maintained the above objections. Another critique on the Howard method was published by Darling.⁴² He was apparently more concerned with the shortcomings of the methods as an analytical procedure than with its use as a control method in a different field. In spite of the accuracy of probably all of Darling's criticisms, the Howard method serves a useful purpose today in keeping the tomato-products industry on a high level.

Despite shortcoming which are obvious to microscopists, the Howard-Stephenson method for determining whether decayed unfit fruit has been used or whether bad practices have existed in the factory, or both, has had a great part in bringing the tomato-products industry to its present high position. This method has helped to get rid of manufacturers of tomato products who have not cared to pay much attention to the condition of tomatoes which they were using. Seizures by the government have cost them much money. It is necessary to be certain that the analyst is competent and understands the procedures for if he does not the packer is working under a false sense of security. Schools are conducted each summer at several places where potential analysts may be trained by those who are competent and who have had experience in counting microorganisms under the microscope. The Department of Agriculture of the Dominion of Canada ⁴³ found the Howard-Stephenson count of value in improving quality of tomato products. While working with manufacturers, a progressive lowering of the mold count was observed during the years 1933 to 1936.

Tice ⁴⁴ used the Howard method in the control of tomato products manufactured in the state of New Jersey. He stated that he found a direct relationship between the methods of manufacture or character of the initial materials used in tomato products and the microscopical results secured by Howard's method. He stated that, "The average of the counts

43. Lochhead. 1938. Prog. Rpt. to the Dominion Agr. Bacteriologist for the Years 1934, 1935, and 1936. Ottawa, Canada, p. 33.

44. Tice. 1918. New Jersey State Board of Health, Ann. Rpt.

on tomato pulp, soup stock or catsup taken from stock which appeared to be acceptable from a visual inspection, were as follows: Molds in 19 per cent of the fields, yeasts and spores 20 per 1/60 c.m.m., bacteria 34,000.000 per cc." He continued, "Our experience has been similar to that of B. J. Howard of the Bureau of Chemistry, United States Department of Agriculture, that in factories where sufficient sorting is in effect, thorough washing is employed and where promptness in handling is observed, the mold count is of greater importance in judging the condition of the raw stock than counts on the other organisms. High counts of yeasts and spores are usually indicative of secondary spoilage."

Insect Fragment Count of Tomato Products. The Federal Food, Drug and Cosmetic Act prohibits shipment in interstate commerce of a food which consists in part or wholly of filthy, decomposed, or putrid animal or vegetable substance. Such a food is adulterated and subject to seizure and destruction. Tomato products which are made from worm and insect infested tomatoes are judged to be adulterated. Consequently, the manufacturer must make certain of clean raw materials and the control officer must develop methods for detecting this sort of adulteration. This effort places a new burden on the manufacturer. The Federal control officials⁴⁵ have stated that the canner must know the degree of infestation of the fruit which he is processing and must use sufficient care in the factory to cope with it.

The insects which cause most trouble are the tomato fruit worm and the tomato pin worm. The former, in sweet corn-producing areas, is known as the corn ear worm. The latter, as its name indicates, burrows into the fruit, leaving a pinhole.

Howard's⁴⁶ Method for Determination of Insect Fragments in Tomato Products.

The following method is fundamentally a method devised by Mr. J. D. Wildman for the recovery of small insects from vegetable greens:

APPARATUS AND MATERIAL REQUIRED

One two-liter Erlenmeyer flask.

One rubber stopper of such size as will just allow it to be crowded down into the interior of the flask. The stopper must be supported by means of a suitable stiff rod ($\frac{1}{8}$ -inch diameter) about three inches longer than the height of the flask.

One Büchner funnel and seven cm. rapid action filter paper with a rather hard finish.

One six-cm. disk cut from a piece of 60-mesh wire screen.

One wide angle field, Greenough type, binocular microscope giving magnifications of about 10X to 30X.

USEFUL ACCESSORIES

One fine point indelible pencil for indicating on the filter paper the location of each insect part as located.

One metal ring $8\frac{1}{2}$ cm. in diameter strung with very fine wire or human hair to form a grid with the strands about 7 mm. apart. This is set over the filter paper which has been placed in a Petri dish for convenience of examination. It serves as a guide in systematically searching the paper over for insect fragments.

One fine teasing needle made by inserting the eye end of a No. 12 sewing needle into a suitable soft wood handle. This is used for manipulating the insect fragments on the filter paper when necessary to secure more suitable view for identification.

45. Harrison. 1937. Canning Age, May 1937.

46. Howard. Private communication.

A miniature coffer dam has proven a valuable aid in order to prevent any portions being lost by being drawn over the margin of the filter disk. A medium soft rubber ring about $\frac{3}{16}$ inch thick is cut of such diameter as to just fit into the Büchner funnel and cover a marginal strip of the filter paper about $\frac{1}{4}$ inch wide. This rubber gasket is held down firmly in place against the paper by a suitable glass cylinder slightly longer than the inside depth of the funnel and kept in place by a thin spring brass yoke clamp which has an inch hole in the center through which the stem of the funnel passes, allowing it to come up and rest against the cone of the funnel. The two arms are bent up in such manner that the ends press down upon the upper edge of the glass cylinder. In order to remove it, it is only necessary to spring the ends back to release the glass collar. The width of the portions forming the arms should be such as will furnish a good moderate pressure without being so strong as to endanger breakage. (See Fig. 2.)

TECHNIQUE OF METHOD

The stopper, by means of the supporting rod, is pressed down into the Erlenmeyer flask. In the case of purée, catsup, etc., 200 ml. of the product to be tested is placed in the flask and 20 ml. of gasoline added. The product and gasoline are then thoroughly shaken together. Water from the tap at about room temperature is run into the flask in such manner as to produce vigorous agitation until the contents rise in the neck of the flask to about the point to which the stopper can be raised. Allow contents to stand for five to 10 minutes, occasionally giving the contents a gentle rotary motion by means of the stopper and rod to facilitate the lighter portions coming to the top. Finally, slowly raise the stopper until it fits firmly into the neck of the flask so as to entrap the gasoline portion and a narrow strip of the aqueous sub-layer, the latter being not over $\frac{3}{16}$ inch deep. (See Fig. 1.) The analyst should avoid entrapping more of the aqueous layer than is needed since, by so doing, an amount of tomato cellular material may be retained that will interfere with filtering and render more difficult the subsequent finding of insect parts. As a guide in this respect it is well to determine by experiment and mark on the neck of the flask the point to which the watery layer should be brought to attain the best results. After the stopper has been raised into place, about 10 or 15 ml. of water is added to the entrapped portion to slightly increase its volume. Carefully pour the entrapped portion onto the filter, underneath which has been placed the wire screen disk. Rinse out the neck of the flask to remove any remaining insect fragments and add to the material on the filter paper. Remove the filter paper and examine the residue under the microscope for insect parts, recording the number of fragments of each kind found and spotting their location by use of the indelible pencil. While search for fragments is being made, it is advantageous to keep the filter paper fairly moist.

In the case of paste, 50 or 100 ml. of product is used, according to concentration. Before the gasoline is added, the test sample is mixed with 200 to 300 ml. of water. After the test has been completed, the results are calculated back to a 200-ml. basis according to the amount of test portion used.

Because of the difficulty of avoiding entrapping so much cellular material as to make the filtering difficult, some preliminary tests have been made in entrapping a somewhat larger amount and pouring it into a 500-ml. Erlenmeyer flask fitted with stopper and rod similar to the large flask. In the small flask a second treatment of the first portion is made before it is thrown on the filter paper. This procedure will reduce the cellular material retained and, from some preliminary tests made, no very appreciable number of insect fragments is lost.

Wilder and Joslyn's "Method for Estimating Worm and Insect Fragments in Tomato Products. After much study these authors recommended the following procedure:

REAGENTS

Sulfuric acid.—12 N.

Potassium permanganate solution.—Dissolve 100 grams of KMnO_4 in 1 liter of warm water and filter.

APPARATUS

Separatory funnel.—1 liter.
Graduated cylinder.—250 ml.
Graduated cylinder.—50 ml.
Filter paper.—7 cm.
Petri dish.—10 cm. diameter.

PROCEDURE

Put 200 ml. of the tomato sauce, juice, or catsup (or 100 ml. of tomato paste) into the separatory funnel. Add 35 ml. of gasoline, stopper, invert, and shake. Open the stopcock slowly to release the pressure. Close the stopcock and shake well until the gasoline is thoroughly emulsified. Open the stopcock to release pressure, close, and invert. Add 200 ml. of the sulfuric acid solution. Move in a rotary motion until the gasoline is well mixed.

Effect on the Total Number of Fragments Found of Varying the Amount of Gasoline (Modified Procedure)

Ml. of Gasoline	Number of Fragments
25	50—42—46
35	54—59
50	53—57—55

Add 150 ml. of the permanganate solution in 50 ml. portions to prevent excessive foaming. After the addition of each portion move the funnel vigorously in a rotary motion until all traces of the permanganate and the manganese dioxide have disappeared. After the last addition, fill the funnel with water and allow to stand for 1 minute.

Drain off the lower layer of water and pulp until the bottom of the gasoline layer is about 2 inches from the stopcock. Add 200 ml. of water, allow to stand for 20-30 seconds, and then drain as before. Add 100 ml. of water and drain again as soon as the gasoline has risen to the surface. If all pulp is not gone, repeat the washing until the water layer is free of pulp.

When the washing is completed, drain off the water until the bottom of the gasoline layer is about one-half inch from the stopcock. Filter the remaining water and gasoline through the filter paper, washing the inside of the funnel well with water. Examine the filter paper under the microscope for worm and insect fragments in the usual manner, as described by Howard.

Microanalysis of Tomato Pulp, Purée, Sauce, and Paste by the Howard Method.⁴⁸
 The following procedure is the Howard method for these tomato products. It serves the same purpose here that the original method does for canned tomatoes and juice.

APPARATUS

(a) *Compound microscope*.—Equipped with good objectives and oculars, giving magnifications of approximately 90, 180, and 500 diameters. For convenience of use the lenses should be adjusted so as to be parfocal. A mechanical stage is highly desirable. It is essential that the combination giving the low magnification be capable of adjustment to give an area of the field of view of 1.5 sq mm. (a circle whose diameter is 1.382 mm.). With the higher powers the working distances must be ample to allow free use of the blood-counting cell.

(b) *Drop-in cross-ruled disk*.—For estimating lengths of mold filaments, an ocular drop-in disk cross-ruled in sixths of the ocular diaphragm opening is desirable.

(c) *Blood-counting cell*.—Ruled in the Thoma or the old Neubauer system of rulings. The so-called “improved” system of Neubauer is not suitable for this purpose.

48. Methods of Analysis, Assoc. Off. Agr. Chem., 1940 edition, 522-524.

(d) *Howard mold-counting cell*.—Constructed like a blood-counting cell but with unruled central disk approximately 19 mm. in diameter.

MOLDS

In making mold counts of tomato products, use the material as is except that clean, mold-free gum may be added to thin products to assist in making more uniform mounts; in the case of tomato products of such heavy consistency as to make observation of mold filaments difficult, mix water to make total tomato solids of diluted product 8.37 to 9.37 per cent. If the product contains salt or other substance that increases solids content materially, take this into consideration in making dilution.

Clean the special Howard cell so that Newton's rings are produced between slide and cover glass. Remove cover and place small drop of the well-mixed sample upon central disk; using knife blade or scalpel, spread drop evenly over disk, and cover with the glass so as to give an even spread.

It is of the utmost importance that the drop be taken from a thoroughly mixed sample and spread evenly over the slide disk. Otherwise, when cover slip is put in place the insoluble material, and consequently the molds, may be more abundant at center of mount. Avoid using a drop that is much greater than is sufficient to fill space between center disk and cover slip. Discard any mount showing uneven distribution, absence of Newton's rings, or liquid that has been drawn across moat and under cover glass.

Place slide under microscope and examine with such adjustment that each field of view covers 1.5 sq. mm. This area, which is of vital importance, may frequently be obtained by so adjusting the draw-tube that the diameter of the field becomes 1.382 mm. When such adjustment is not possible, it is sometimes necessary to have a mechanic make an accessory drop-in ocular diaphragm with the aperture accurately cut to necessary size. The diameter of area of field of view can be determined by use of a stage micrometer, or by employing the rulings on the blood-counting cell. In order to use latter method it is necessary to bear in mind that a square whose diagonal is 1.382 mm. has sides of approximately .977 mm. Hence the millimeter scale on the blood-counting cell can be used by such adjustment that the circle of the field of view cuts off necessary amount from each corner of the mm.-ruled square. When the instrument is properly adjusted, the quantity of liquid examined per field is .15 c.mm. (.00015 ml.).

From each of two or more mounts examine at least 25 fields taken in such manner as to be representative of all sections of the mount. Observe each field, noting presence or absence of mold filaments and recording result as positive or as negative, as case may be. No field should be considered positive unless the aggregate length of not more than three of the filaments present exceeds approximately $\frac{1}{6}$ of diameter of field. Calculate proportion of positive fields from results of examination of all observed fields and report as percentage of fields containing mold filaments.

YEASTS AND SPORES

Fill graduated cylinder with H_2O to 20-ml. mark and add sample till level of mixture reaches 30-ml. mark. Close graduate, or pour contents into Erlenmyer flask, and shake vigorously 15-20 seconds. To assure thoroughness the mixture should not fill more than $\frac{3}{4}$ of container in which shaking is performed. For tomato sauce or pastes, or products running high in number of organisms or of heavy consistency, use 80 ml. of water with 10 ml. or 10 gm. of sample. In case of exceptionally thick or dry pastes, it may be necessary to make even greater dilution.

Pour mixture into beaker. Thoroughly clean blood-counting cell so as to give good Newton's rings. Stir thoroughly contents of beaker with scalpel or knife blade and after allowing to stand 3-5 seconds remove a small drop, place it upon the central disk of the blood-counting cell, and cover immediately with cover glass. Discard any mount showing uneven distribution, absence of Newton's rings, or liquid that has been drawn across moat and under cover glass. Allow slide to stand not less than 10 minutes before beginning to make the count. It is customary to make the count with a magnification of 180-220 diameters.

Count number of yeasts and mold spores on $\frac{1}{2}$ of ruled squares on disk (this amounts to counting the number in 8 of the blocks, each of which contains 25 of the small ruled squares). Total number thus obtained equals number of organisms in $\frac{1}{60}$ c.mm. ($\frac{1}{60,000}$ ml. of original product) if a dilution of 1 part of sample with 2 parts of H_2O is used. If a dilution of 1 part of sample with 8 parts of H_2O is used, multiply the number by 3. In making the counts, the analyst should avoid counting twice the organisms that rest on a boundary line between two adjacent squares.

BACTERIA

Determine the number of rod-shaped bacteria from mounted sample used in "Yeast and Spores," but before examination allow sample to stand not less than 15 min. after mounting. Use magnification of approximately 500 diameters.

Count and record number of bacteria having a length greater than $1\frac{1}{2}$ times their width in an area including 5 of the small squares. Count number in 5 such areas, preferably 1 from near each corner of ruled portion of slide and 1 from near the center. Determine total number of rod-shaped bacteria in the 5 areas and multiply by 480,000. This gives number of this type of bacteria per ml. If a dilution of 1 part of sample with 8 parts of H_2O instead of 1 part of sample with 2 parts of the H_2O is used in making up the sample, then total count obtained in the 5 areas must be multiplied by 1,440,000. The bacteria sometimes exhibit slight motion and thus may present momentarily an end instead of a side view. For this reason, it is necessary to keep them under observation long enough to establish their true character. Thus far it has proved impracticable to count the micrococci present as they are likely to be confused with other bodies frequently present in such products.

Linden's⁴⁹ Method for Examination of Canned Tomato Products. This procedure proposed by Linden is recommended for tomato products and other products with a similar acidity. Linden stated that modifications in treatment could include: (a) Before being cultured, samples submitted for examination for incipient or advanced spoilage should be examined microscopically in order to obtain some information as to the types of organisms present. Gram's stain is useful as most spoilage organisms in this class of foods are Gram-positive. Determination of pH may be useful, but is of limited value as only slight reaction changes occur in these products. (b) Normal appearing cans submitted for examination for commercial soundness or keeping quality should be incubated at 30°C. if less than 14 days has elapsed since the product was packed. Additional incubation at this temperature to insure at least 14 days' incubation is desirable. When no 30°C. incubator is available, incubation at an average room temperature of 25°C. may suffice. (c) Samples examined for the presence of other than spoilage organisms require incubation at 37°C. in culture media suitable for the detection of organisms capable of causing spoilage of non-acid foods. Products such as tomato pastes, purées, and ketchups are often used as packing media (sauces) for non-acid products and may be responsible for spoilage under these changed conditions of pH. The following method is recommended:⁵⁰

CULTURING PROCEDURE

A. PHYSICAL EXAMINATION AND PREPARATION OF CAN

1. Note and record all marks of identification, either embossed on the can or appearing on the label.

2. Remove the labels. Record any physical defects such as improper closure, leaks, bad seams, buckling, or other abnormal conditions such as springers, flippers, or swells.

3. Scrub the entire surface of the container with a brush, using soap and warm water, and wipe off the surface with 70% alcohol prior to opening.

4. If possible, open the end of the container that does not bear the cannery code marks. For sterilization at the site of opening, expose the container top over the flame of a Bunsen burner, using a rotary motion to obtain an even distribution of

49. Linden, 1938. Assoc. Off. Agr. Chem. J. 21, 454-457.

50. Assoc. Off. Chem. J. 21 (1938), 72.

heat and to prevent scorching of contents. (This procedure also tends to minimize the danger of contamination from inrush of air when the container is opened.) Do not subject hard swells to heating before opening. (It is suggested that swollen containers that exhibit considerable pressure be chilled before they are opened to reduce spurting.) After cleansing swollen cans, apply the treatment described by Fellers.⁵¹ (As an alternative it is suggested that after the mechanical cleansing with soap and water the container be thoroughly cleaned with 70% alcohol. Phenolic solutions may interfere with the organoleptic examination of the can contents because they tend to mask the odors.)

B. REMOVAL OF SAMPLE

1. *Opening of container.*—After sterilizing the site of opening, make an entrance with an appropriate type of opener, which has also been sterilized by direct flaming. For products of heavy consistency, such as tomato paste, preferably use openers of the spiral or circular type, which cut around a central puncture. (Openers that cut around the can seam are less desirable because of greater surface exposure and danger of contamination.) When fluid products are sampled, make the opening by a suitable metal punch of appropriate diameter to insure an aperture that will permit free access of the sampling pipet. Further details on sampling devices are discussed by Tanner.⁵²

2. *Inoculum.*—Sample liquid or semi-liquid food products with sterile untapered pipets or inverted tapered pipets of suitable capacity. (The untapered pipets should have minimum dimensions of 350 mm. in length and 5 mm. inside diameter.) Sample solid or semi-solid food products with sterile spatulas, long-handled spoons, or other instruments, as suggested by Tanner, depending on the character of the food under examination. Use pipets only for products of such viscosity as to permit transfer of the inoculum into the culture media by gravity. As suggested by Tanner, use a sample consisting of a minimum of 15 grams or 15 ml. of the food material and divide it into aliquots for duplicate culturing in each of the different culture media used in the examination.

3. *Sampling of product fractions.*—When representative inocula are desired from both the liquid and solid parts, transfer the solid component of the sample to the culture medium with forceps sterilized by flaming and use culture media in large test tubes (100×25 mm.) or in wide-mouthed jars or bottles.

C. CULTURE MEDIA

Because of their acid nature many products in this class are subjected to the limited processing designed only to prevent spoilage. This is done to preserve the color, flavor, and texture of the foods. In some instances the products are filled into the cans while hot and receive no further heat processing. Two main groups of microorganisms encountered in the spoilage of this class of canned food products are the aciduric bacteria and the yeasts. Viable bacteria capable of producing spoilage in non-acid foods but rendered inactive in acid foods have frequently been responsible for the reporting of false positive results in examinations for spoilage in acid canned foods. Use the following media adjusted to a reaction below pH 5.0 for the detection of spoilage organisms:

1. *Acidurio spoilage bacteria.*

*Acid-Meat Medium*⁵³

Dstilled water.....	1000 ml.
	grams
Ground fresh lean beef.....	500
Proteose peptone.....	5
C. P. NaCl.....	5
C. P. Dextrose.....	10

51. Fellers. 1936. Assoc Off. Agr. Chem. J. 19, 430.
52. Tanner. 1936. Idem 432.
53. Modified acid meat medium for tomato products and other acid canned foods—to 1,000 ml of broth as above add 11 gm. citric acid and 12 gm. of potassium citrate. This will give a pH of 4.4 to 4.5 (private comm. from Linden).

Infuse the beef-water mixture overnight in the refrigerator. Heat in Arnold or boil for 30 minutes. Strain through several layers of cheese cloth and press out broth, retaining the meat press cake. Add distilled water to the infusion to make up to 1 liter. Add the peptone and heat in Arnold or boil 10 minutes. Filter, and add salt. Acidify with C. P. lactic acid to pH 4.7, add the dextrose, and filter. Distribute the pressed-out beef remaining from the infusion into medium sized test tubes (150×20 mm.), approximately 2 grams into each tube, and add 10 ml. of the broth. Sterilize in the autoclave at 15 lbs. pressure for 15 minutes (final reaction should be pH 4.8. Prior to using, boil the tubed medium for 10 minutes to expel absorbed oxygen and cool promptly in a water bath.

As an alternative enrichment medium use digest-yeast-tomato juice, described in last year's report,⁵⁴ modified by the addition of 0.5 per cent proteose peptone and adjusted to pH 4.8-5.0 with C. P. lactic acid.

The preparation of plate cultures is optional, and when desirable add 2% agar to the broth formula given above, dissolve by heating, filter, and adjust reaction to give final pH 5.0. Sterilize in an autoclave at 15 lbs. pressure for 15 minutes.

2. *Bacteria inhibited below pH 5.0.*—Use a medium essentially the same as the acid meat medium with reaction adjusted to pH 7.2. (This medium, when rid of excess free oxygen by boiling and prompt cooling just prior to use, has been found satisfactory for the growth of anaerobes, aerobes, and facultative bacteria.

3. *Yeast spoilage.*

Clarified malt extract medium.⁵⁶

Dry malt extract (Difco).....	100 grams
Distilled water	1000 ml.

Dissolve the powdered malt extract in the water by heating in an Arnold sterilizer, or on the water bath. Adjust to pH 4.7 and cool to 50°C. Add slowly 100 ml. of a 5% suspension of Bentonite (colloidal clay) and mix vigorously. Hold at 50 to 75°C. for 30 minutes, then filter through a fluted paper filter until clear. Heat the filtrate in the autoclave 10 minutes at 15 lbs. pressure, and filter through paper to remove any precipitate formed. Distribute into tubes or flasks. For a plating medium, dissolve by heating, 2% agar-agar in the clarified broth, and filter if necessary through cotton and cheese cloth. To avoid further precipitation sterilize at 10 lbs. pressure for 15 minutes and cool promptly. (Bacto Malt Extract Broth can now be obtained in convenient dehydrated form and may be substituted for the above medium.)

4. *"Flat-sour" spoilage bacteria.*

Medium for detection of "flat-sour" organisms

The bromocresol purple dextrose tryptone medium, recommended by Cameron in his Report on Culture Media for Non-Acid Products⁵⁶ has been found useful in the detection of thermophilic bacteria occurring in acid canned foods.

D. INCUBATION

Incubate all cultures for the detection of spoilage organisms for at least 72 hours at 30°C. For the detection of non-aciduric bacteria, incubate at 37.5°C. for at least 48 hours. For the occasional "flat-sour" spoilage encountered in such products as tomato juice, incubate for thermophilic anaerobes at 56°C. for at least 48 hours.

E. CULTURE STUDY

Use the Manual of Methods for Pure Culture Study of Bacteria of the Society of American Bacteriologists as a guide for study of microorganisms obtained in the cultural procedure described.

CHAPTER 17

MICROBIOLOGY OF BREAD

The use of bread by man goes back to earliest times. Many different kinds have been made. Wittmack¹ examined Egyptian bread 4,400 years old with the microscope and observed remains of yeast cells and bacteria indicating that it was fermented. Bacteria similar to butyric acid bacteria were particularly noticeable. Starch was largely gelatinized. Unchanged starch grains were found, however, which gave characteristic reactions with iodine. More recent reports on examination of some old breads have been made by Grüss,² who isolated several yeasts.

Bread sold in America is a clean food because it is wrapped. In 1913, the National Association of Master Bakers took the position that wrapping bread in waxed or paraffin paper was not to be recommended as it held the moisture upon the surface of the bread and produced injurious effects upon the quality of the product. It was stated that the wrapping of bread in porous paper, which allows a gradual loss of moisture and ventilation, may be used with satisfactory results generally, except in the cases of Vienna and rye bread, the wrapping of which impairs the crispness and flavor of the crust. The sanitarian, however, has a different interest. Young³ pointed out the ease with which unwrapped bread may be contaminated as it is carried about. Bread in some foreign countries may not be as clean a product as in America. Wibaux⁴ inspected 100 bakeries in the Lille region and found very unsatisfactory conditions. He believed that tuberculosis was a disease which might be disseminated by pastries since the temperatures at which they were baked might not be sufficient to sterilize them. Introduction of machinery in the baking industry in France is greatly changing the hygienic qualities of French bread, just as it did in America.

TYPES OF BREAD

The various kinds of bread may be classified in different ways. One convenient grouping is leavened and unleavened bread. Leavened bread is "raised" by the formation of gas resulting from chemical reactions (baking powder) or biological fermentation. The first bread baked by man was probably little more than pulverized grains and other materials mixed with sufficient water to yield a sticky dough, molded, and baked. Later, it was learned that desirable characteristics were obtained by allowing the dough or sponge to ferment. In the early days fermentations were induced in one batch by using a little fermented dough from a previous baking. Many times this procedure resulted in undesirable changes, caused by foreign organisms which overgrew the desired fermenting agents. An

example of unleavened bread would be the Mexican *tortilla* or crackers, as used in the United States.

“**Sauerteig.**” This bread is made by seeding the sponge or dough with fermenting microorganisms from a portion saved from the previous baking. Owing to formation of acids from microbial fermentation and appearance of a well-established characteristic odor, it is called “sauerteig” or sour dough. This method is used for making many of the coarser whole-meal breads. The bacteria in “sauerteig” according to such investigations as Lehmann⁵ and Wolffin, are varieties of *Aerobacter levans* (*Bacterium levans*) and *Escherichia coli*. Levy⁶ believed that the bacteria all fell into the coliform group. He concluded that in the case of spontaneous fermentation and fermentation caused by leaven, *Bacillus coli albidoliquefaciens* and *Bacillus coli luteoliquefaciens* were present in addition to a typical *Escherichia coli*, all of which produced acid and gas. Porosity was said to have been caused by these three organisms. When leaven was used, yeast was said to be the main fermenting agent. Holliger⁷ believed that *Aerobacter levans* was not identical with *Escherichia coli*. He stated that *Aerobacter levans* may be isolated by means of a two-per cent dextrose bouillon. It may be distinguished from *Escherichia coli* by gelatin liquefaction, which takes place in about 12 days. *Aerobacter levans* may also be distinguished by formation in dextrose broth of a gas with two-thirds carbon dioxide and one-third hydrogen, while *Escherichia coli* shows the reverse. Data have also been reported by Wolffin,⁸ Burri and Holliger,⁹ Teichert,¹⁰ Kossowicz,¹¹ and others.

About 200 lactic acid bacteria were isolated by Knudsen¹² from the dough from 20 Danish bakers. Some of them formed only lactic acid, while others formed acetic acid, alcohol, and carbon dioxide. The latter strains were said to give sour dough and bread their special aroma. One strain referred to as *Betabacterium* was considered to be the specific organism of “sauerteig.” It was always found in the meal, but only in small numbers. In order to have it gain ascendancy over other forms, ideal conditions had to be maintained. In order to make certain that the organisms are present, some old dough should be put in; infection may also occur from the apparatus. Levy and Wolffin classified the various forms of bacteria in “sauerteig” as forms of *Aerobacter levans* in addition to *Escherichia coli*, which was generally found to be present.

Lactic acid is not the only acid formed in this fermentation. Seliber¹³ observed another but did not identify it. The aroma and flavor of these breads was reported by Komm and Lehmann¹⁴ to be due to biacetyl and acetone, the same substances which have been found in dairy products. A

heterogeneous flora was observed by Seliber, Bychkovskaia, and Volfson¹⁵ in dough from Leningrad bakeries. Many of the bacteria were acid formers. Such results suggest that this dough fermentation is a symbiosis rather than a pure-culture matter. However, these authors seemed to secure good results with pure cultures as leavening agents. They believed they had isolated "true sour dough bacteria." Results of experiments by Nikolaev¹⁶ were quite similar. Combinations of the right bacteria and yeasts gave high-quality bread. Bacteria from wheat and rye leaven were similar. Most of the species were organic acid producers.

Black Bread. This is a coarse whole-meal bread, usually leavened with "sauerteig." Its microbiology probably differs little from that of "sauerteig," discussed above. Coarse wheat or rye flour is usually used. Perhaps the results of a bacteriological investigation of sour rye bread, reported by Budinov¹⁷ are pertinent. Only one bacterium (*Bacillus mesentericus pani viscosi* II) was found to be common to both samples, but representatives of the following groups were identified: (1) peptonizing bacteria which turned the dough from a thick to a more plastic state; (2) yeast, which caused the dough to rise; and (3) lactic or acetic bacteria, on which the sour taste and smell of the black bread depend. Cultivation of the isolated forms on sterilized dough was not successful, owing to the difficulty of obtaining sterilized flour. For complete sterilization of flour, one-half hour's heating in an autoclave under two atmospheres of pressure was necessary; this treatment, however, changed the flour and made it unsuitable for dough.

Another coarse bread prepared by the Indians of Brazil (Lieske¹⁸) is also apparently leavened by a mixture of yeasts and bacteria. This bread is known as "jamin-bang." The fermentation is made up of an acid and alcoholic fermentation and is affected by organisms on maize or in the river water in which the grain is soaked. Two yeasts and a bacterium were isolated by Lieske. Lindner, who discussed this fermentation, considered the occurrence of a bottom-fermentation yeast in the tropics as unusual.

Self-Rising (Salt-Rising Bread). This bread has been made for generations in America. As suggested in the name, the fermentation is a spontaneous one, since no leavening agent is added. Kohman,¹⁹ who reviewed the literature quite thoroughly, reported some interesting experimental work.

Some believe that the fermentation is due to wild yeasts which enter the dough from the air. In support of this are investigations of Mitchell,²⁰ Bailey²¹ and others. That it is a bacterial fermentation is supported by the work of Heinemann and Hefferan²² and Kohman.¹⁹ The middle ground, that both yeasts and bacteria are concerned, was taken by Leh-

mann,²³ Peters,²⁴ and perhaps Harrison.²⁵ Lehmann isolated an organism which he called *Aerobacter levans* (*Bacillus levans*). Heinemann and Hefferan isolated a bacillus from corn meal which had many of the characteristics of *Lactobacillus bulgaricum* (*Bacillus bulgaricus*). They proved that the organism came from the corn meal and believed that, the large amount of acid formed by this bacillus (1.65 per cent) from milk, united with the inorganic salts to form carbon dioxide. The extensive work of Kohman¹⁹ indicated that bacteria were the important agents in the fermentation. Kohman stated that the leaven in salt-rising bread was not yeast, as stated in literature on the subject, but consisted of certain species of bacteria which aerate the bread by decomposing some of its constituents, principally sugar, into gaseous products. He did not favor the opinion that the carbon dioxide resulted from acids and sodium bicarbonate. The microbic flora involved varied greatly, depending upon the temperature to which the meal was subjected in setting the "batter." The organisms that predominate in the batter when it is made by stirring the meal into boiling milk or water are only occasionally found upon plates made from batters that were not subjected to temperatures which destroy nonsporebearing organisms. The chief source of the bacteria is not the air and utensils, as has been suggested in the literature, but the corn meal used in making the batter. One organism was isolated which in pure culture produced the gas necessary to properly aerate bread. This bacterium seemed to be a member of the *Escherichia coli* group and was never found in batters that were heated to 75°C.(167°F.). It in all probability, belongs to the same group as the organism described by Wolffin and Lehmann which they called *Aerobacter levans*. This organism could be propagated in liquid media such as milk or could be grown in batter and subsequently dried, to be used in the preparation of bread. When the liquid used in making the batter was sufficiently hot to bring the temperature of the batter to 75°C.(167°F.) or higher certain sporebearing organisms prevailed which readily produced the gas necessary to aerate bread. These bacteria soon lost their gas-producing power when kept in liquid media or when transferred to fresh media at intervals of 12 to 24 hours. From this fermenting batter no culture was isolated that retained its ability to produce gas when kept in the liquid state. A dry product consisting for the most part of starchy material was prepared, however, which could be used at will in making uniform bread. Bread made with leaven, *i.e.*, the "sauerteig" method differed from salt-rising bread in that the leavening is due to yeasts and not to bacteria. It is a question then whether gas-forming bacteria, which are present, are desirable or not. The two breads differ also in that salt-rising bread is made from fresh materials each time, while in making leavened bread a portion of the dough is saved to start the fermentation of the next baking. The gases produced by the "salt-rising" bacteria, as found in these experiments, consisted of nearly two-thirds hydrogen and rather

23. Lehmann. 1894. Centbl. Bakt., 15, 350-354.

25. Harrison. 1902. Ontario Agr. Bull., 118.

more than one-third carbon dioxide and no hydrocarbons. The losses of materials, owing to decomposition and volatilization of some of the constituents, are much smaller in salt-rising bread than in bread made with yeast, and the losses in the latter vary with the amount of fermentation to which it is subjected. The difference in the losses of materials in the preparation of the two kinds of bread is to be explained by the fact that (1) there is no alcohol found in the former; (2) owing to inherent difference in the nature of the fermenting agents involved, it is subjected to far less fermentation; and (3) the gases are much lighter.

Woodward²⁶ believed that the fermentation occurring in salt-rising bread may be due to the presence of one or more organisms accidentally in the corn meal from which the batter used in starting the bread is made, or introduced in some similar way. The organisms isolated were not yeasts but belonged to some other group. Koser²⁷ reported a very interesting investigation of a commercial "bread starter" advocated for the preparation of salt-rising bread. Bacteriological examinations seemed to indicate that his leavening agent was *Clostridium welchii*. The organism in the starter was compared with an authentic strain of *Clostridium welchii* and both the authentic strain and that isolated from the starter were used for making bread. The bread prepared with the strain of *Clostridium welchii* of known authenticity could not be distinguished from that prepared with the starter. The commercial starter contained 1,000 organisms per gram. Bread from bakeries using this starter was found to contain considerable numbers of viable spores. Koser stated that in view of the possible pathogenicity of *Clostridium welchii*, it might be better to employ an organism the use of which was beyond question from the public-health standpoint. This is another illustration of the fact that some of the pathogenic anaerobes may not be harmful when taken by mouth. This organism which was found in a bread starter is known to be commonly present in the intestinal tract and in foods. Albus,²⁸ for instance, has reported *Clostridium welchii* as the organism responsible for the gassy fermentation of Niszler cheese. Koser estimated that the sponge at one stage of its preparation might contain from 1 to 100 million cells of *Clostridium welchii* per gram. His work further suggests that perhaps those who have tried to find the real agent responsible for the "self-rising" bread fermentation, have erred by not looking for anaerobic bacteria.

Microbiology of Flour and Meal. Microorganisms in flour and meal have much to do with the bacterial content of bread. As would be expected, the flora of flour has been found to be heterogeneous. Thom and LeFevre²⁹ found common molds such as *Aspergillus repens*, *Penicillium luteum*, *Penicillium oxalicum*, *Aspergillus flavus*, *Aspergillus tamari*, *Aspergillus niger*, and others, to be present in corn meal. Various yeasts were also found. As long as the moisture was kept below 13 per cent, the molds did not develop, but above 15 per cent, *Aspergillus repens* began to be active.

27. Koser. 1923. J. Infect. Dis., 32, 208-219.

28. Albus. 1924. Abs. Bact. 8, 13.

29. Thom and LeFevre. 1921. Abs. Bact., 5, 10.

Similar observations were reported by Bailey and Thom,³⁰ Bell,³¹ Street,³² and McHargue.³³ Arnoldow³⁴ found that practically all kinds of bacteria and molds would develop when the water content was above 17 per cent. *Aspergillus fumigatus* was found by Sartory and Sartory³⁵ in flour with a musty odor. Kühl³⁶ isolated butyric acid bacteria from abnormal flour.

The bacterial content of flour may be high. Turley³⁷ reported counts which varied from 310,000 to 5,200,000 bacteria per gram. Results of a comprehensive investigation on this subject have been recently reported by Amos and Kent-Jones^{38a}. These authors studied at some length, the technic that should be employed. Freshly milled patent flour contained less than 20,000 bacteria per gram, straight-run flour less than 50,000, and lower grades less than 300,000, growing at 37°C. (98.6°F.). Storage of flour resulted in a lowering of the content of microorganisms, but the rate depended on the amount of water present and the temperature. Especially interesting was the report that *Escherichia coli* of fecal origin was present in flour. It was suggested that the organism might originate in the water used for washing the whole wheat. This was proven by analyzing the water used for this purpose, in several mills. Members of the *Bacillus mesentericus* group are almost always present. Holtman³⁹ observed a reduction in microbial content of flour during milling. Most flours on the market contained fewer than 8,000 microorganisms per gram.

Kent-Jones and Amos³⁸ reported results of a comprehensive examination of flour. Preliminary examinations by them revealed the presence of from 2,000 to 200,000 bacteria per gram developing at 37°C. They distinguished between bacteria developing at 37°C. (blood-heat) and those organisms developing at lower temperatures ("cool") mainly as a matter of convenience. When freshly and normally milled, patent flour showed less than 20,000 bacteria developing at 37°C. per gram straight-run flour less than 50,000, and lower grades up to 300,000 or more. Bacteria growing at lower temperatures were usually present in greater numbers. During storage both types of organisms decrease the rate depending on the moisture content and the temperature of storage. The types of bacteria were not especially significant, with exception of *Bacillus mesentericus* which causes "ropy bread." These investigators, then, reported a great variation in numbers of bacteria in flours. Results of another extensive investigation by Barton-Wright⁴⁰ also indicated a reduction in viable microorganisms in stored flours. His work was on two different low-grade English flours stored in bins with two different moisture contents. He used the Kent-

Jones and Amos method for microbial analysis substituting a synthetic medium for the organic medium used by the former investigators. Barton-Wright did not secure the high counts reported by Kent-Jones and Amos, the highest being 57,000 per gram. During storage bacterial numbers always decreased while fungal numbers increased. The later increased to a maximum when the moisture content was 16 per cent or over. Mustiness was due to fungi and not bacteria. Over 90 per cent of the fungi belonged to the genus *Penicillium*.

Rancidity of flour, according to Gustafson and Parfitt⁴¹ is not related to total numbers of bacteria either in the case of plain or self-rising flours. The total number of bacteria was practically the same in both types of flour. Storage caused the number of bacteria to decrease.

The conditions under which flour is stored have much to do with behavior of bacteria in it. Among the more important is humidity. Barton-Wright and Tomkins⁴² observed that flour exposed to relative humidities between 80 and 90 per cent was attacked by *Penicillium* sp.; bran under the same conditions was attacked by *Penicillium* and *Aspergillus* sp. at room temperatures. No mold growth was observed in flour of 16 per cent moisture content, the equilibrium moisture content at 75 per cent relative humidity. Critical moisture content for mold growth increases as the temperature decreases. Mold growth was prevented when flour was exposed to relative humidity of 79 per cent at 20°C. (68°F.) when moisture content of the flour was 16 per cent, to a relative humidity of 82.5 per cent at 15°C. (59°F.) when the moisture content was 16.5 per cent, and to a relative humidity of 85 per cent at 5°C. (41°F.) with a moisture content of flour of 17.4 per cent. Wheat flour over several years was found to contain no canned food spoilage bacteria by Yesair and Reed.⁴³ Not many samples were examined, however.

McWhorter's⁴⁴ Method for Counting Spores. This method was described by McWhorter for enumerating spores and may be applied to various food products. The method requires two persons, an observer and a recorder, but is very rapid and eliminates some of the experimental error. Select a thin, round cover glass and with India ink rule across it two parallel lines a millimeter or less apart. In the middle of the cover draw a third line perpendicular to and joining the first two, thus forming a narrow letter H in the center of the cover. Drop the cover onto the "stop" of an ordinary 10 × eyepiece as though inserting a micrometer disc. Such a cover, unlike an ordinary micrometer disc, does not perceptibly interfere with definition, a factor of importance when observing hyalin spores. Place the slide, which should be prepared so as to give a fairly uniform distribution of spores, in position on a mechanical stage having convenient right and left movement. Arrange the eyepiece containing the cover slip so that the parallel lines coincide with the right and left movement of the stage. With a three or four mm. lens, select, in the region well to the left of the center of the preparation, a field showing abundant spores. Suppose there are five kinds of spores in the mount; assign a letter to each kind. Move the slide from left to right so that the spores appear to be slowly travelling along between the two lines. Call off to the assistant the proper letter for each spore passing by the vertical line within the

parallel lines. Let the assistant record the letters on plotting paper conveniently divided off into 50 or 100 squares. This method will enable a record to be made almost as fast as one can talk. Of course, simply counting the letters will give the percentage of each type of spore. This procedure will obviously eliminate some of the experimental error common in "field counts," and is much faster.

Kent-Jones and Amos'³⁸ Method for Bacterial Examination of Flour. A wide-mouthed, glass-stoppered bottle of eight-ounce capacity; two narrow-mouthed, glass-stoppered bottles of four-ounce capacity; and a 100-ml. measuring cylinder are thoroughly cleaned. The measuring cylinder is plugged with cotton-wool and then, together with the bottles, is placed in the hot-air sterilizer. One one-ml. and two five-ml. pipettes are cleaned, plugged with cotton-wool, and inserted in a metal container, which is then also placed in the hot-air sterilizer. The sterilizer is then raised to a temperature of 150°C.(302°F.) and maintained thus for one hour. A .5 per cent solution of sodium chloride in distilled water is prepared and sterilized by steaming for two hours. By means of the measuring cylinder, 100 ml. of the sterile salt solution (after cooling) are measured into the eight-ounce bottle, and 45 ml. into each of the four-ounce bottles. Ten grams of purified sand are ignited strongly in a platinum capsule and poured, while hot, into the bottle containing the 100 ml. of the salt solution.

Ten grams of the flour are weighed out on a sterile watch glass and transferred, by means of sterile paper, to this same bottle. The bottle is then shaken vigorously for two minutes. When the bulk of the sand has settled (it settles very rapidly), one of the sterile five-ml. pipettes is used to transfer five ml. of the suspension to one of the bottles which contain 45 ml. of the salt solution. The bottle is then shaken vigorously. Then, by means of the remaining sterile five-ml. pipette, five ml. of the liquid are transferred to the remaining bottle, which is vigorously shaken. Finally, one ml. of this liquid is transferred, by means of the sterile one-ml. pipette, to a sterile Petri dish. A 10-ml. tube of sterile nutrient agar is melted in boiling water, allowed to cool to 45°C.(113°F.), the plug removed, the neck of the tube "flamed," and the contents of the tube poured into the Petri dish. The agar and the extract are mixed by rocking the dish, which is then placed on a flat surface while the agar solidifies. The dish is then placed, in an inverted position, in a blood-heat incubator (37°C.). A count is taken at the end of 48 hours.

Barton-Wright^{44a} used formation of a pellicle on nutrient broth as the method of estimation instead of counting. Otherwise his technic conforms so closely to that of Kent-Jones and Amos that it need not be given in detail here.

Hoffman's Method for Estimating Bacteria in Flour. Hoffmann,⁴⁵ in order to determine the number of bacteria in flour, shook 7.5 grams in 300 ml. of sterile water for one-half hour. After this the mixture was plated in the usual media.

Toxins for Yeasts in Flour. According to different investigators, agents exist in flour which retard the action of yeast as a leavening agent. Brewers' yeast is especially susceptible while distillers yeast is less so. Baker and Hulton⁴⁶ tried to find why brewers' yeast when used in bread making, did not produce a degree of fermentation equal to that produced by distillers' yeast. When comparative tests were made with both brewers' and bakers' yeast and wheat flour, using distilled water as a menstruum, practically no fermentation took place in the case of brewers' yeast while distillers' yeast fermented well. When tap water was employed however brewers' yeast fermented without any trouble. Experiments were then conducted

46. Baker and Hulton. *J. Soc. Chem. Ind.*, 28, 778-784.

with inorganic salts, potassium sulfate and others in distilled water. Here it was found that fermentation occurred with brewers' yeast and that these salts had a protective or antitoxic effect towards the toxins contained in the wheat flour. The use of these salts produced no acceleration of fermentation with bakers' or distillers' yeast. The effect produced by tap water was probably brought about by the presence of acid calcium carbonate. Brewers' yeast cultivated three times in distillers' mash took on some of the characteristics of bakers' yeast. Baker and Hulton believed that the yeast acquired an immunity to the toxins in the flour. Thus there is an explanation why brewers' yeast did not give good results with raw flours.

In another paper the same investigators reported the results of experiments carried out with invert sugar, aqueous flour extract, invert sugar and flour, aqueous flour extract and flour, distillers' wort (rye and maize), cold aqueous extract of distillers' malt, and unboiled malt wort prepared from brewers' malt. It was found that potassium sulfate was without effect as far as the actual acceleration of fermentation was concerned with invert sugar solutions and that its function is only that of a protective agent against toxins. A distilled water extract of the toxin was destructive to yeast and this toxicity could be held in check by the addition of potassium sulfate. Fermentation of a sugar solution by brewers' yeast was stopped by adding flour, but if potassium sulfate was present fermentation proceeded. Brewers' yeast was acted upon strongly by the rye flour toxin, but the latter was not so soluble as the toxin of wheat. Fermenting an aqueous solution of flour by brewers' yeast and adding flour checked fermentation. Bakers' yeast fermentations were not affected. A malt distillers' wort containing rye flour and maize was toxic to brewers' yeast, but this toxicity could be destroyed by boiling. High temperatures destroyed the toxicity of the malt but the process of germination did not. The toxicity in the flour may also be partially destroyed by heating at a temperature of 100°C. (212°F.) for some hours. Baker and Hulton sought to simulate the toxic action of the flour toxin by adding potassium cyanide to the fermentation but found that potassium sulfate exerted no protective effect.

After summarizing the work already published on this subject, LeCourt⁴⁷ described his own researches on the localization of the toxin in the wheat and the various attempts to isolate it. The poison appeared to accompany the glutenin portion of the seed protein without being glutenin itself. The question was discussed as to whether the toxin was of a protein nature. Hayduck⁴⁸ concluded that it was, since it was destroyed by trypsin digestion—a fact verified by LeCourt, who, however, considered this no proof, since if it is admitted that the poison is a product of degradation from the nontoxic protein, it must also be admitted, as Willstätter has shown for enzymes, that the poison consists of a colloidal support and an active chemical group and that toxicity disappeared when the colloidal support was destroyed. Numerous attempts to adsorb the toxin on kaolin, norit, alumina, and hydrate of iron were described. It was noted that the

47. LeCourt. 1927. Diss., Paris; Ann. Brasserie 26.

48. Hayduck. 1908. Allg. Ztschr. f. Bierbrau u. Malzfabrikat 36, 505-507, 513-516.

toxicity of wheat flour towards yeast was only manifested in the presence of fermentable sugars and was a function of their concentration. Among the conclusions of LeCourt may be mentioned the following: In the presence of sugar the poison acts rapidly on bottom fermentation yeast at 2°C.(35.6°F.), but at 27°C.(80.6°F.), it acts slowly, both on bottom yeast and bakers' yeast. Certain races of yeast exist, which, even when cultivated in wort, remain insensitive to the action of the toxic substance of flour. By washing the glutenin with acidulated water it was found possible to remove the poison from it. Wheat flour toxin acts in very small doses and is comparable in this respect to enzymes. It has no action on zymase but in the presence of sugar kills yeast fairly rapidly, the toxicity, however, being diminished when the acidity of the medium is increased. All salts are able to neutralize the toxicity at sufficient concentrations. Hayduck's early work on this subject was confirmed by LeCourt who found that the toxic substance was definitely associated with glutenin. It was very potent and only a very small amount was necessary to destroy the action of yeasts.

More definite information on these bodies in flour has appeared in recent literature. Stuart and Harris^{48a} reported isolation of a crystalline substance of protein-like nature from wheat flour which showed marked fungicidal activity for *Saccharomyces cerevisiae* causing death of cells in concentrations of 0.005 mg. per ml. and higher. Similar results were secured with pathogenic fungi *Debaromyces nadiformis* and *Endomycopsis albicans*. This activity was believed to be restricted to yeasts and yeast-like fungi. These results help to explain the yeast-killing activity of wheat flour, much of the literature of which has been reviewed above. Failure of dough to rise is thus explained. That these agents may exert their activity on yeast enzymes was suggested by Kneen and Saudstedt.^{48b}

Soy Bean Flour and Meal. This is known to harbor many microorganisms, some of which are spoilage organisms for foods to which it is added. Thermophilic bacteria contained therein have caused spoilage of meat preparations. Those who recommended its addition to foods which are to be preserved in any of several ways must consider this possibility. Samples analyzed by Kaberg, in the author's laboratory for canned food spoilage bacteria, were found to vary greatly in content of flat sour-producing sulfide spoilage, and thermophilic anaerobes. Practically all of the samples had flat sour-producing bacteria; two samples were entirely free, however. Sulfide spoilage bacteria were few in number and thermophilic anaerobes were present in only two samples. One manufacturer claimed to have developed a process which eliminated most of the thermophilic species. In processing soybean oil meal the temperature may reach 132.2°C.(270°F.) for a short time while the flour may reach 115.6°C(240°F.). This might not sterilize the products but would destroy many nonsporeforming species.

Microbiology of Other Meals and Flours. Many of these products are added to various foods which are processed in different ways. Few results

48b. Kneen and Saudstedt. 1943. J. Amer. Chem. Soc. 65, 1247.

of general bacteriological examination have been published. Most of the investigations have been carried out for some definite purpose as is the case in the canning industry where it is important to learn whether spoilage bacteria are present. The various types are discussed in Chapter 19 where the generally accepted procedures are also given. Yesair and Reed ⁴³ used them on sugar, starch, cracker meal, cracker flour, wheat flour, corn flour, tapioca flour, and a few other types. The percentage of satisfactory samples was high. Flat sour-producing bacteria were the only types found to be present. Yesair and Reed believed that such materials should be subject to regular laboratory control before they were used. Corn flour was observed by Yesair and Cameron ^{43a} to contain more thermophilic bacteria than wheat flour. They believed that satisfactory flours could be secured for addition to canned meats and other non-acid canned products.

Yeast Cells in Bread Doughs. The function of yeast cells in dough is to produce gases which leaven it. Whether yeast increases in numbers in dough or whether it remains constant in numbers respiring enough to produce leavening gases, has been argued by baking technologists. According to Hoffman, Schweitzer, and Dalby ⁴⁹ whose method is quoted below, Lindet ⁵⁰ tried to answer the question using the standard agar plate. Owing to clumping of yeast cells, the results secured with this method are usually too low. Geere and Geere ⁵¹ proposed a microscope method while Simpson ⁵² used a hemacytometer.

Activity of yeast cells in dough depends somewhat on the conditions under which they are stored before use. Thiessen ⁵³ observed better activity over a longer time when pressed yeast and dried yeast were stored at 4.4 to 10°C. (40 to 50°F.) than when stored at room temperature of 21.1 to 23.9°C. (70 to 75°F.). Pressed yeast retained its activity for several months when frozen and resumed almost normal biological activity when used under favorable conditions. Only a small percentage of dead cells was present but this increased on longer storage.

Hoffman, Schweitzer, and Dalby's ⁴⁹ Method for Counting Yeast Cells in Bread Dough. The method was given by the authors as follows:

PROCEDURE

Take a 20-gram sample of dough, place in a two-liter beaker, add 1,460 ml. of distilled water, five ml. of chloroform, and 10 grams of sodium chloride. The chloroform is added to prevent further growth of the yeast cells while the counts are being made, but, inasmuch as it does not mix with the solution, no account need be taken of it when considering the dilution. The salt is added to bind and hold the gluten in a ball and thus prevent its disintegration during the washing process.

Wash the starch and yeast cells from the gluten by hand for a period of at least 10 minutes, taking care to incorporate all shreds and particles of the original 20-gram sample.

Place the gluten ball in a graduated cylinder and add distilled water to a volume of 500 ml. Again wash the gluten ball in this volume of water for another period of

10 minutes, in order to remove the yeast cells enmeshed therein, and add this solution to the first wash water. Thoroughly agitate this yeast and starch suspension, which now totals 1,960 ml., and transfer 49 ml. to a 200-ml. flask and stopper to prevent evaporation. Add one ml. of standard Carbol Fuchsin solution, made up according to the directions given in the U. S. Pharmacopoeia, to the 49 ml. of the suspension in the Erlenmeyer flask. This gives a final dilution of 20 grams of dough in 2,000 ml. of solution, or a 1-to-100 dilution.

Allow the stained solution to stand four or five hours or, if convenient, overnight, before the counts are made. This permits the color to stain the yeast cells thoroughly. When examined under the microscope at the end of that period, it will be found that the yeast cells have taken on a deep, dark red color, while the starch cells are only colored a faint pink. Any small particles of gluten material will also be colored a dark red but they can easily be differentiated from the yeast cells because of the regular contour and the cellular structure of the latter. Likewise, it is possible to distinguish yeast cells from small or similarly shaped starch cells by the fact that the latter are always clear and translucent and show no cellular structure.

During the time that the 50-ml. portion of the "starch-yeast" suspension is being stained, place the gluten ball remaining from the two washings in the graduate and add distilled water to bring the volume to 188 ml., which is about one-tenth the volume of the main suspension. It is better to work with more concentrated solutions in this case because of the very small number of yeast cells still remaining in the gluten ball. Add .2 ml. of concentrated hydrochloric acid to the solution and allow to stand overnight. At the end of the overnight period the gluten will be dissolved almost completely, and upon shaking a colloidal suspension of the gluten is obtained, while the yeast cells are unchanged. To 47 ml. of this suspension add three ml. of Carbol Fuchsin solution and let stand overnight. It is necessary to use considerably more of the staining solution in this case because the colloidal gluten seems to prevent the yeast cells from readily taking the stain. Even with this amount, the cells are colored only a faint pink, instead of a dark red, as in the case of the "starch-yeast" suspension. However, the minute gluten particles remain colorless in this solution and show no cellular structure.

For this work in our laboratory a Thoma-Zeiss haemocytometer is used, and the counting chamber is a Thoma-Levy modification of the Burkner apparatus with two Neubauer rulings. Immediately before the actual counting, the flasks containing the stained solutions are shaken vigorously to bring into suspension all particles and cells which may have settled out. With a stirring rod, drops are removed and one placed on each of the Neubauer rulings and one on the intervening moat. The plano-parallel cover glass is placed in position with the thumb and forefinger and then one end of it is rapidly lifted up and down several times in order to expel any air bubbles and also to insure a uniform distribution of the solution. It is essential that this precaution be taken. The prepared slide is now allowed to set for a few minutes before the counting is started in order that the yeast cells may settle out upon the ruled surface of the counting chamber. The counts are made with the high-power four-mm. objective.

Each Neubauer ruling of the Thoma-Levy counting chamber is divided into nine large squares of one mm. each. The number of yeast cells in such a square is counted and an average taken of from eight to 12 such counts. Since there is a space of only .1 mm. between the cover glass and the ruled disc, it is necessary to multiply this average count by 10 to find the number of yeast cells in one cubic millimeter of the solution. This figure must be multiplied by 1,000 to convert to milliliters, and again by 100 because of the dilution of the solution. Consequently, when the average count is multiplied by 1,000,000 the number of yeast cells present in one gram of the original dough is obtained.

Each of the larger square-millimeter squares in the Neubauer ruling is further subdivided into 16 small squares. One of these small squares completely covers the field of the microscope when the four-mm. objective is used. In actual practice, therefore, the number of yeast cells in each small square is counted and the number put down in its corresponding place in a table representing the larger square-millimeter

square. The sum of 16 such counts gives the number of cells in a square millimeter. It has been found preferable to count the cells in one or not more than two sq.-mm. squares, after which the counting chamber is cleaned and a fresh slide prepared. This prevents errors owing to evaporation of the solution, and it is for this same purpose that a drop of the solution was placed in the moat. In counting, the cells lying on the lines above and to the right are counted, never those on lines below or to the left. Yeast buds mature speedily in the dough into normal cells and exert the same influence on the dough as do the parent cells. For this reason, in counting, each bud that is large enough to be unmistakably recognized as such is counted as a single cell.

AN EXAMPLE OF COUNTING

Each square represents a square millimeter on the Neubauer ruling. Thus, the 16 sets of figures inside the square represent the number of yeast cells in the 16 small divisions into which each square millimeter of the ruling is subdivided. Illustrated yeast-cell counts follow:

CALCULATION OF NUMBER OF YEAST CELLS PER GRAM OF DOUGH

The total number of yeast cells per gram of dough is obtained by adding the number of yeast cells found in the "starch-yeast" suspension and the number found in the "gluten-ball" solution, which is divided by 10 before being added to the count obtained from the "starch-yeast" suspension. For example, if 98.5 cells per sq. mm. were found in the "starch-yeast" suspension, and 18.8 cells per sq. mm. in the "gluten-ball" solution, the total count would be 98.5 plus 1.88, which is 100.4 cells per sq. mm. Multiplied by 1,000,000 the result is 100,400,000 yeast cells per gram of dough.

Hoffman, Schweitzer, and Dalby ⁴⁹ found that yeast definitely grew in dough, the greatest growth occurring between the second and fourth

hour in a straight-dough formula. Optimum baking results were secured with 1.75 per cent of yeast based on the flour. Ammonium chloride and calcium sulfate showed a nutritive effect on yeast.

Neumann and Knischewsky's⁵⁴ Method for Counting Yeast Cells in Dough. Turley⁵⁵ outlined the method as follows: Remove 15 grams of dough from the batch and place in 150 ml. of water. The gluten separated by washing 25 ml. of this suspension was mixed with 25 ml. of iodine solution (150 ml. water, 1 gram KI, and .005 gram I), and diluted to 400 ml. with distilled water. One drop of this suspension was placed on the ruled area of a yeast counting apparatus or hemacytometer.

Turley's⁵⁶ Method for Counting Yeast Cells in Dough. In order to obtain representative sample, collect 20-gram pieces of dough from different parts of the batch and place in a covered dish. Weigh one gram sample of the dough by taking bits from the different samples which were collected.

Place the sample in a 600-ml. beaker with 200 ml. of distilled water (acidified with .1 ml. normal hydrochloric acid) at a temperature of 65°C. (149°F.). Add .5 gram of soluble pepsin and hold at 65°C. for 15 minutes. This may be done on a water bath. At intervals, the digestion may be aided by breaking up the bits of dough with a rod. Digestion is complete in 15 minutes. The digestate should then be thoroughly stirred and 10 ml. withdrawn with a 10-ml. pipette graduated in tenths. Of the amount withdrawn 4.8 ml. are transferred to a 20-ml. beaker and .05 ml. of melted phenol added. Hold for one minute at 65°C. with stirring. Allow the phenol to act for an additional two minutes. Then add .15 ml. of Loeffler's methylene blue and allow to act for one minute. Then thoroughly stir the sample and transfer a drop to the ruled area on a counting chamber. Count and record the yeast cells in a row of 20 squares. Computation is made in the usual manner.

Simpson's⁵⁶ Method for Counting Yeast Cells in Fermenting Dough. This is a modification of Turley's method. The dough from 20 grams of flour is rapidly cut into small pieces, put into a 600-ml. conical flask with 400 ml. of .05 N hydrochloric acid containing .2 per cent of pepsin scales, and placed in a water bath maintained at 40°C. (104°F.). The flask is repeatedly well shaken during digestion which generally takes from 45 minutes to one hour; and the shaking is continued until all pieces of dough have been dispersed. A few drops of brom-thymol blue indicator are added, the liquid is titrated with normal sodium carbonate solution to a greenish-blue color. The flask is placed in a boiling water bath, being shaken at first until the temperature of its contents comes to 90°C. (194°F.), after which it is left in the bath for another five minutes. After cooling to 65°C. (149°F.) 10 ml. of a five-per cent dilution of diastatic malt extract (about 100° Lintner) are added, digestion being continued for 10 minutes at 65°C. After cooling to room temperature one ml. of one per cent methylene blue solution is added, the flask well shaken, and its contents transferred to a 500-ml. graduated flask, the washings from the conical flask being used to make up 500 ml.

After appropriate dilution of an aliquot portion, the yeast cells are counted with a haemacytometer in the usual manner.

Not much has been published on the influence of the particular species of yeast on bread flavor. Wardall⁵⁷ used 33 pure strains of yeasts and could observe no difference in the flavor of bread leavened by them. She regarded the time of incubation as too short for the development of any special flavor. This subject could well be studied again. The availability of commercial compressed yeast, produced under rigid conditions, has made the manufacture of bread more uniform. The baker finds it necessary to have an active, uniform supply of yeast.

DEFECTS OF BREAD

Bread, like other foods, may undergo a number of deteriorations, some of which may be due to defective raw materials, while others may result from infection after the bread has been made and baked.

Veikko⁵⁸ found the spoilage in barley bread was in part due to *Bacillus mesentericus*, the maximum temperature of growth of which was 50°C. (129.2°F.) and to other organisms with a growth temperature of 62°C. (143.6°F.). Microorganisms which liquefied gelatin caused most rapid spoilage of bread. A comprehensive discussion of defects of bread has been published by Nikolaev.⁵⁹ Morison and Collatz⁶⁰ reported that cut surfaces of ropy bread present a strong odor which is decidedly unpleasant and not unlike that of decomposed or overripe melons. The center of the crumb is soft and discolored. This discoloration is of a brownish hue and the softened portions can be drawn out into long threads from four to six inches in length when touched with a glass rod or other instrument.

ROPE IN BREAD

This may be a troublesome defect of bread. It has been prevalent during times of emergency when coarse and more uncommon flours have been used. The literature has become quite voluminous and is in fair agreement as to the cause and methods of prevention. One of the first to study the problem was Laurent⁶¹ who isolated a bacterium from ropy bread in Belgium, to which he gave the name *Bacillus panificans*. It was a sporeforming organism which survived the temperatures attained in bread during baking. The organism was isolated from many different materials, including cereals and soil. Laurent reproduced the defect by inoculating the organism into dough and was probably the first to show that addition of vinegar to bread prevented development of the organism. Kratschmer and Niemilowicz⁶² reported *Bacillus mesentericus vulgatus* as the cause of ropy bread in Vienna. It was probably the same organism described by Laurent. These observations have been confirmed in the United States by subsequent investigators. *Bacillus mesentericus* is a strict aerobe which grows well on ordinary media. It is actively proteolytic. Vogel⁶³ isolated organisms to which he gave the names *Bacillus mesentericus pani viscosus* I and II. Russell⁶⁴ reported that *Bacillus mesentericus vulgatus* was the causal organism. Russell found that after the loaf had been baked for an hour and a half that the center had not reached a temperature high enough to destroy the organism. He further believed that the organism was present in the yeast. Eckles,⁶⁵ by means of thermometers, confirmed Russell's statements about the temperatures reached in baking. The highest temperature attained by the loaf was 97°C. (206°F.) after about an hour's baking. *Bacillus*

panis was isolated by Fuhrmann⁶⁶ as the etiologic agent in ropy bread. Honig⁶⁷ believed the rope to be derived mainly from the outer membrane of the cells themselves. Watkins'⁶⁸ investigation pointed to *Bacillus mesentericus* as the cause of the trouble. Breads containing much bran were believed to be especially susceptible to rope.

The work of the investigators just referred to was confirmed by Juckenack,⁶⁹ Kreis,⁷⁰ Svoboda,⁷¹ Harrison⁷² and Fisher and Halton⁷³ Experiments by Allen⁷⁴ in which some 15 aerobic sporeforming bacteria quite similar to *Bacillus subtilis* were inoculated into bread doughs, showed that all of them produced rope in 30 hours when the bread was stored at 25°C.(77°F.). In one case where the oven was held at 204°C.(399.2°F.) the center of the loaf did not reach 100°C.(212°F.).

Source of Bacteria Causing Ropy Bread. While almost every ingredient used in bread making may contribute spores of rope-forming bacteria, under present commercial practice, flour, yeast, and malt are the main sources. Flour practically always harbors these bacteria as shown by results of various investigators. Powdered milk has also been reported to contribute rope-producing bacteria to the sponge.⁷⁶

Methods for Prevention of Ropy Bread. This involves keeping the spores of *Bacillus mesentericus* out of the dough, or preventing their development if they are present. General cleanliness in the bakery is, of course, desirable. Ashby and Prickett,⁷⁶ in addition, suggested destruction of the spores of *Bacillus mesentericus* with germicides. Among those which may be used vinegar, hypochlorites, and formaldehyde were suggested. Vinegar in concentrations as low as one per cent was said to be germicidal toward rope-producing bacteria in the vegetative stage. When spores are present even vinegar containing as much as 2.5 per cent of acetic acid did not destroy them. Ashby and Prickett reported that hypochlorite solution containing 1,000 p.p.m. of available chlorine destroyed the most resistant spores.

Prevention of rope in bread has, in general, been accomplished by addition of acetic acid, .3 to .7 pound per sack of flour (280 lb.). Fisher⁷⁷ stated that this was equivalent to three and one-half to eight and one-half pounds of white vinegar per sack. He stated that two pounds of acid calcium phosphate per sack would completely prevent rope while one and one-half pounds would prevent it for five or six days. Watkins stated that the minimum amount of acid to prevent rope was three pounds per sack. Lactic acid had to be used to the extent of .6 pound. After studying

various possible preventatives of rope in bread, Bunzell, Forbes, and Sherman⁷⁸ stated that 100-grain white vinegar in amounts of .66 per cent (3.82 pints per 600 pounds of flour) was more than adequate to prevent development of rope. Results of extensive experiments have been reported by Kirby, Atkin, and Frey.⁷⁹ They found that vinegar and calcium acid phosphate prevented development of rope at a pH of about 5 to 5.15, whereas tartaric acid must be used in quantities to give a higher acidity—a pH of about 4.7. Kirby and his colleagues were led to state that vinegar must possess some specific substance inimical to rope-producing bacteria other than its effect on acidity. Kirby, *et al.* also showed that vinegar was quite effective against molds on bread when it was applied to the surface of the loaf. When it is added to the dough, it is volatilized during baking and perhaps neutralized by bread constituents. Further information on the effect of acids on these organisms may be found in publications by Thomas,⁸⁰ Cohn, Wolbach, Henderson, and Catheart,⁸¹ Weimershaus and Svenson,⁸² and Stuchlik.⁸³

The other method of fighting rope in bakery products is through plant sanitation and destruction of the spores in the bakery with germicides. Ashby and Prickett,⁷⁶ after ruling out those which could not be used because of toxicity, odor, and color, mentioned hypochlorites, vinegar, and formaldehyde as possible ones. Hypochlorites were found to be good for regular use and formaldehyde for emergency use. Vinegar was objectionable because of its corrosive effect on metals.

Morison and Collatz⁶⁰ studied the influence of certain acids and acid salts on development of rope in bread and on the quality of the bread so treated. The acids used were acetic, lactic, hydrochloric, and sulfuric. The salts used were potassium dihydrogen phosphate and acid sodium sulfate. The source of the rope-producing organisms was a badly infected flour. Bread made from this flour was incubated in a moist chamber at 37°C. (98.6°F.) for three days. The bacterium responsible for ropy bread is generally conceded to be *Bacillus mesentericus*. Many strains are strongly proteolytic on gluten media prepared from washed gluten. The gluten is reduced, according to Morison and Collatz, to a slimy mass which gives off the characteristic odor. These investigators used acetic acid in amounts from 10.4 to 1.04 ounces per barrel of flour with a varying pH from 4.8 to 5.4. When used at the rate of 10.4 ounces (.33 per cent) rope development was prevented but the quality of the bread was poor. When 5.2 ounces (.17 per cent) of acetic acid was used, the bread was of good quality but rope developed in five days. At lower concentrations of acetic acid, rope developed more quickly. The experiments with lactic acid in larger amounts (22.21 ounces of 70 per cent lactic acid or about .5 per cent of anhydrous lactic acid) prevented rope development but yielded bread of

poor quality. Results with sulfuric and hydrochloric acids were generally unsatisfactory. Sodium acid sulfate (20.67 ounces to 196 pounds of flour or 66 per cent) produced a poor bread with inhibition of rope. Lower amounts gave better quality bread but rope developed sooner. Attempts to use combinations of above-mentioned salts were generally unsatisfactory.

In a comparative study of calcium acid phosphate and calcium propionate, O'Leary and Kralovec⁸⁴ found the latter to be from two to three times as effective as the former. Rope formation became more important as the number of bacteria increased from six to 1,300 per gram of flour. More than 1,300 spores per gram did not increase the rate of development of rope. These were well-controlled experiments.

Hoffman and his associates⁹⁰ proposed standards for spore counts of bread ingredients. Bread baked with six bacteria per gram of flour (twice Hoffman's standard adjusted to the formula used) developed symptoms very slowly. At one-third Hoffman's standard, no rope developed in 10 days. The pH of bread did not influence the rate of rope development if the inoculum used was high. With lower inoculum, the rate of development varied markedly when pH 5.37 was compared with pH 5.87. The inhibitory effects of both calcium acid phosphate and calcium propionate were found to be influenced by the amount of inoculum used and by the pH of the bread. Calcium propionate was found to be two or three times as effective as calcium acid phosphate. The difference in retarding effect between the two rope inhibitors was greatest at high pH values.

Watkins'⁸⁸ Method for Detecting the Organisms in Flour Which Cause Ropy Bread. The test is rapid and Watkins stated that there is little possibility of a sound flour failing to pass the test because they do not yield appearances of ropiness in the time proposed as a limit. Ten large test tubes (six inches by one inch) are thoroughly boiled in water for one hour, washed and drained. When drained, sterilize in the oven at 232°C.(449.6°F.) for three hours. The tubes should be thoroughly sterilized. Cool and then place into each tube a finger of bread three inches by one-half inch, but from the center of the same two-day-old loaf. The average weight of each loaf should be five grams. Moisten with distilled water and plug the tubes. Sterilize by boiling in water on three successive days. To test the flour, two grams are well mixed with water and placed in boiling water 30 minutes. To the series of 10 tubes add successively from one to seven ml. of the flour mixture, leaving three tubes to serve as checks. Number the tubes in rotation. Incubate at 28°C.(82.4°F.) and at the end of 24 hours examine for ropiness.

Kornauth's⁸⁵ Method for Detecting Organsims in Flour Which Cause Ropy Bread. This is a modification of Kühl's method and is carried out as follows: 280 grams of flour, 140 ml. of salt water, and .6 gram of yeast are made into a loaf. After baking, the loaf should be stored at 25°C.(77°F.) for 48 hours. If the organisms causing ropy bread were present in the flour, the loaf will have a characteristic odor. Several loaves should be made at the same time with sound flour as a check.

Lloyd's⁸⁶ Method for Detecting Ropy Bread Organism in Flour. Lloyd and his colleagues used the following method:

1. 300 ml. of distilled water are placed in a 500-ml. flask which is plugged with cotton and sterilized in the autoclave.

84. O'Leary and Kralovec. 1941. *Cereal Chem.* 18, 730-741.

85. Kornauth. 1912. *Arch. f. Chem. u. Mikros.* 5, 267-270.

86. Lloyd. 1921. *J. Hyg.* 19, 380-393.

2. 100 grams of flour are weighed out and shaken into sterile water with constant stirring.

3. The flask containing the water is well shaken.

4. Tubes containing from 10 to 20 ml. of nutrient agar are melted, four of these being allowed for each sample of flour.

5. Four ml. of the flour emulsion are removed from the flask with a sterile graduated pipette, one ml. being placed in each of the four tubes of melted agar which are placed in boiling water for 20 minutes.

6. The contents of each tube are then poured into sterile Petri dishes which are incubated at 38°C.(100.4°F.) for 24 hours.

Brahm's⁸⁷ Method for Detection of Organisms in Flour Causing Ropy Bread. To 300 ml. of sterile water in a 500-ml. flask add 100 grams of flour or meal and shake thoroughly. Then add one ml. of this suspension or emulsion to tubes of liquefied agar and heat in boiling water for 20 minutes. After this, pour the contents of the tubes into sterile Petri dishes. After 24 hours' incubation, colonies of *Bacillus mesentericus* should develop. Less than 12 colonies per ml. indicate a satisfactory flour; between 12 and 50 colonies indicate a flour which is unfit for bakery purposes.

Voitkevich's⁸⁸ Method for Detecting Rope-Forming Bacteria in Flour. Inoculate .2 gram of suspected flour into 10 ml. of sterile water; pasteurize at 75°C.(167°F.) for 10 minutes. Inoculate the contents of the tube into a loaf and incubate at 33°C. (91.4°F.) for 40 hours. The presence of *Bacillus mesentericus* is indicated by changes in the appearance of the loaf, as well as by microscope examination. Voitkevitch observed a striking seasonal prevalence of ropy bread; 35 per cent of 612 samples examined in summer and 10 per cent of 131 samples in winter showed the organism.

Bunzell and Forbes'⁸⁹ Method for Testing Ropiness of Bread. This method was devised for determining with considerable accuracy the incidence of rope-forming organisms in bread. The method is based upon the formation of the enzyme catalase by bacteria in the bread. It is necessary to assume that the bacteria which survive baking are members of the mesentericus group. Bunzell and Forbes devised an apparatus with which catalase activity could be measured.

Hoffman, Schweitzer, and Dalby's Method for Estimating Rope-Producing Bacteria in Flour. A dilution method was suggested by Hoffman, Schweitzer, and Dalby⁹⁰ for estimation of spores of rope-producing bacteria in flour and other materials. Two hundred grams of the material to be examined are transferred aseptically to a 250-ml. glass-stoppered bottle. About 10 grams of sea sand are added; then add 96 ml. of distilled water to the dilution bottle. This provides a dilution of 1 to 48 and may be used to determine presence of spores up to 200 per gram. Shake the dilution bottle vigorously 50 times, each excursion being about one foot up-and-down. Immediately after the sand has settled pipette 4.8 ml. of the 1 to 48 dilution into another 250-ml. glass-stoppered bottle containing 95.2 ml. of distilled water. This provides a dilution of 1 to 1,000 and is used to determine the presence of spores in numbers between 250 and 20,000 per gram. Pipette the following amounts of the 1 to 48 dilution into culture tubes containing sterile broth:

Ml.	Dilution	Ml.	Dilution	Ml.	Dilution
4.8	1-10	1.2	1-40	.48	1-100
2.4	1-20	0.8	1-60	.32	1-150
1.6	1-30	0.6	1-80	.24	1-200

Shake the 1-1,000 dilution 25 times as previously described. Prepare a third dilution of 1 to 100,000 from the 1 to 1,000 dilution. Use this dilution for determining the presence of spores between 25,000 and 100,000.

87. Brahm. 1921. Ztschr. f. Gesam. Getriedew. 13, 105-113.

88. Voitkevich. 1926. Rev. in Biol. Abs. 3 (1929), 1388.

89. Bunzell and Forbes. 1930. Cereal Chem. 7, 465-472.

90. Hoffman *et al.* 1937. Ind. Eng. Chem., 29, 464-467.

Pipette the following amounts of the 1 to 1,000 dilution into culture tubes containing nutrient broth:

Ml.	Dilution	Ml.	Dilution
4.0	1-250	.2	1-5,000
2.0	1-500	.1	1-10,000
1.0	1-1,000	.05	1-20,000
0.4	1-2,500		

Shake the 1 to 100,000 dilution 25 times and pipette the following amounts of this dilution into culture tubes containing nutrient broth:

Ml.	Dilution
4.0	1-25,000
2.0	1-50,000
1.0	1-100,000

Heat the tubes of nutrient broth in the steam sterilizer for 30 minutes at 100°C. (212°F.). The time is considered from the time the temperature of the sterilizer reaches 100°C. Incubate the tubes for 48 hours at 37.5°C. (99.5°F.). Examine them at the end of 48 hours for the presence of surface growth. Presence of a pellicle or any surface growth constitutes a presumptive test for the presence of rope-producing spores. Record the results as plus or minus for each dilution. The number of rope-producing spores per gram of material tested is taken as the reciprocal of the highest dilution giving positive results. Then the results should be recorded as indicating the number of spores equal to the number of spores equal to the reciprocal of the dilution next lower than the highest one giving a positive result. The quantitative estimation is not complete unless the two highest dilution tubes show negative results.

A long series of dilutions are ordinarily unnecessary in routine examinations for sorting our suspicious samples. The 1 to 48 dilution is adequate. Strict bacteriological technic must be observed throughout the test; all glassware and media must be sterile and the work must be carried out in dust- and draft-free laboratories.

Amos and Kent-Jones'⁹¹ Method for Counting Spores of Rope-Producing Organisms in Flour. This is a modification of a method from Hoffman. It was outlined by Amos and Kent-Jones as follows:

Method. The details of the method finally adopted are as follows: The bottles, pipettes and measuring cylinder are sterilized by heating at 150°C. (302°F.) for two hours. The .5 per cent sodium chloride solution is sterilized by boiling in a plugged flask for one hour. Four hundred ml. of the sodium chloride solution are measured into a sterile 16-ounce glass-stoppered bottle and 100 ml. into a sterile eight-ounce glass-stoppered bottle. Twenty grams of purified silver sand are heated to redness in a platinum capsule for some minutes, and then poured, while hot, into the liquid in the 16-ounce bottle. Twenty grams of the flour are weighed out on a sterile watch glass and transferred by means of sterile paper to the 16-ounce bottle. This bottle is then shaken vigorously for two minutes. Volumes of two ml. and one ml., respectively, of the suspension are then added immediately, by means of a sterile one-ml. pipette, to five ml. tubes of the broth (for preparation of the broth, see later). The bottle is reshaken once or twice and, by means of a sterile pipette, 20 ml. of the suspension are added at once to the liquid in the eight-ounce bottle, and this bottle then well shaken. By means of a fresh sterile one-ml. pipette, volumes of 4, 3, 2.5, 2, 1.7, 1.5, 1.3, 1.2, and 1 ml., respectively, of this dilution are then added to five ml. tubes of the broth. The bottle is shaken once or twice before the withdrawal of each of the above quantities. Each tube is taken individually, the contents thoroughly mixed, and the tube at once placed in a bath of boiling water, so that the level of the water is above the level of the liquid in the tube. The tubes are allowed to remain in the bath for 20 minutes, and during this time the water is kept boiling. On removal of the tubes from the bath their contents are thoroughly mixed and they are then

91. Amos and Kent-Jones. 1931. *Analyst*. 56, 573-585.

placed in an incubator kept at 37°C.(98.6°F.). The contents of the tubes are well mixed three or four times during the first 24 hours' incubation. At the end of 48 hours' incubation the tube is reported as positive or negative according to whether the contained broth shows a pellicle or not. The number of rope spores per gram is taken as the reciprocal of the smallest fraction of a gram of flour giving a positive result. If, as sometimes happens, a negative result is obtained with a quantity of flour greater than the smallest amount giving a positive result, then the number of spores per gram is taken as the reciprocal of the quantity next greater than the smallest amount giving a positive result. The quantity of flour corresponding with the various volumes used is as under:

2	ml. of primary suspension—	1/10 gm. flour
1	ml. of primary suspension—	1/20 gm. flour
4	ml. of 20:100 dilution—	1/30 gm. flour
3	ml. of 20:100 dilution—	1/40 gm. flour
2.5	ml. of 20:100 dilution—	1/48 gm. flour
2	ml. of 20:100 dilution—	1/60 gm. flour
1.7	ml. of 20:100 dilution—	1/70 gm. flour
1.5	ml. of 20:100 dilution—	1/80 gm. flour
1.3	ml. of 20:100 dilution—	1/92 gm. flour
1.2	ml. of 20:100 dilution—	1/100 gm. flour
1	ml. of 20:100 dilution—	1/120 gm. flour

If the flour contains more than 120 spores per gram a further dilution is made.

Cleaning of Used Tubes. The tubes are heated in a steam sterilizer for at least 30 minutes. The plugs are then removed, the contents discarded, and the tubes well washed out with hot water, a test-tube brush being employed. The tubes are then placed in a bath of mercuric chloride solution (1:1,000) and allowed to remain there for some hours. On removal from this bath, the tubes are washed out 10 times with water, drained, plugged, and heated at 150°C. for one hour and a half.

Preparation of Nutrient Broth. Ten grams of B.D.H.* bacteriological peptone, 5.4 grams of "Difco" beef extract, and 9 grams of A. R. sodium chloride are dissolved in a liter of distilled water, and the pH adjusted to 7.2 to 7.3. The solution is boiled and filtered, and the filtrate made up to one liter. The medium is distributed in five-ml. quantities in sterile test-tubes of five-eighth-inch diameter and sterilized for 10 minutes on three successive days in a steam sterilizer. In order to make certain of the complete absence of rope spores in the sterilized tubes of broth, they are placed in a blood-heat incubator for 48 hours; any of the tubes that show pellicle formation are discarded.

Amos and Kent-Jones⁹¹ reported the presence of *Bacillus subtilis*, an organism almost identical with the rope-producing bacteria in flour. It may cause trouble in examination of flour for rope-producing bacteria because it grows quite like the latter. It does not however, cause ropy bread. To distinguish the organisms Amos and Kent-Jones suggested preparation of agar slant cultures from pellicles. The form of growth permits distinction between these two organisms. *Bacillus mesentericus vulgatus* was said to form a greyish-white growth which is at first moist and "blister-like," later becoming dried and unwrinkled. *Bacillus subtilis* gives a whitish, spreading growth; the edges of which, viewed under the low power of the microscope, appear as an interwoven mass of fine hairs.

The organisms causing ropy bread are present in all flours. Neumann and Knishchewsky⁹² found them in all specimens irrespective of the grade.

* British Drug House, Ltd.

92. Neumann and Knishchewsky. 1910. Ztschr. Gesam. Getriedew. 3, 187-191; continued in later numbers.

They also observed the effect of acids on these spoilage organisms. Henderson,⁹³ Williams,⁹⁴ and Zeckendorf⁹⁵ also added acids. Hydrogen-ion concentration is then very important in the baking industry, as shown by Sorensen.⁹⁶ Others who have studied this question are Kayser,⁹⁷ Perotti and Comanducci,⁹⁸ Beattie and Lewis,⁹⁹ Henderson,¹⁰⁰ Cohn *et al.*,¹⁰¹ Seligmann,¹⁰² Lloyd,¹⁰³ Beatty,¹⁰⁴ Fisher and Halton,⁷³ and Amos and Kent-Jones.³⁸ The last-mentioned found rope bread organisms in much of the bread in England. This is also true for bread and flour in America. Many samples were examined in the summer of 1923 in the author's laboratory by Miss Strauch and later in 1928-1929 by Mr. Beier. All contained many spores of rope-producing bacteria. Hoffman, Schweitzer, and Dalby⁹⁰ examined hundreds of flour samples of patent, clear, rye, and whole-wheat flours, the spore counts of which were as high as 150 per gram, although many samples were free. For about 10 years after this work was done, spores of rope-producing bacteria have been less frequent in flour. This condition was attributed to better methods of harvesting and milling grains. Kent-Jones and Amos³⁸ also found many rope-producing bacteria in flour. Three varieties of these organisms were reported. They also reported the presence of *Bacillus subtilis* in flour. This organism is almost identical with *Bacillus mesentericus* but is not involved in rope formation.

While flour is generally considered to be the source of spores of rope-producing bacteria in bread, it is now known that malt, yeast, and other materials may also contribute these organisms. Hoffman, Schweitzer, and Dalby⁹⁰ mentioned appearance of rope in bread even when spore-free flour was used. This prompted counts on all ingredients of bread. Spores of rope-producing bacteria were found in yeast and malt in significant numbers but were absent in other ingredients, such as sugar, milk, shortening, and water. Daily examination of yeast shipments yielded spore counts as high as 20,000 per gram. This condition prompted the manufacturers of pressed yeast to produce a product which has 10 or fewer spores per gram of yeast.

Malt extracts have also been dangerous potential sources of rope-producing bacteria. Hoffman *et al.* reported as many as 10,000 spores per gram. Here again the manufacturers of malt so improved their product that it is now relatively free of spores.

Tentative standards for interpretation of spore counts of flour and other materials were reported by Hoffman *et al.* Counts of 20 per 100 grams of flour, 100 per gram of yeast and malt, and 10 per gram of other

ingredients are considered objectionable. These suggested standards are quite rigorous.

After developing a procedure for determining the number of rope-producing bacteria in flour, Amos and Kent-Jones⁹¹ found that the content of these bacteria in flour, unless particularly high, is of little significance in outbreaks of rope formation in commercial practice. While it is helpful to supply a flour with few such bacteria, of greater importance are the systems of fermentation, baking, and bread cooling. In fact, Amos and Kent-Jones believed that the importance of these factors was not sufficiently recognized in the trade. When rope-bread troubles appeared, they advised a short system of fermentation, a liberal quantity of yeast, avoidance of a low temperature in the dough, and avoidance of slack doughs. Amos and Kent-Jones did recognize some slight value in knowing whether flour was heavily laden with spores of rope-producing bacteria. The baker might have an abnormal flour or might not be doing something which should be done. O'Leary and Kralovec,⁸⁴ on the other hand, believed the number of spores in the flour to be important, even from as few as six spores up to 1,300 per gram of flour.

Effect of Baking on Spores of Rope-Producing Bacteria in Bread. Spores of *Bacillus mesentericus* are not destroyed by baking but are reduced somewhat in numbers. Kent-Jones and Amos⁹⁸ found viable spores in normal loaves. Their procedure was to remove small samples of bread aseptically from the center of loaves and to incubate them in sterile tubes containing a little moist wool at 37°C. (98.6°F.).

Sour Bread. The abnormality is due to the production of acids in the dough. This usually occurs in dough which has been allowed to ferment or rise too long. Different explanations have been offered to explain sour bread. An old theory had it that the alcohol formed in the bread by the yeast was oxidized to acetic acid. While it is a reasonable explanation, there is little evidence to support it. Jago and Jago¹⁰⁵ stated that sour bread was due to bacterial fermentations, chief among which is the lactic acid fermentation. The bacteria which bring about these fermentations are introduced either in the yeast or flour or by dirty utensils. Sour bread is probably due to bacterial fermentation instead of yeast. The bacteria leave acids while the yeast forms carbon dioxide.

Chalky Bread. This was first observed by Lindner¹⁰⁶ and is characterized by the formation of white spots. The white spots were found to consist in part of a fungus to which the name *Endomyces fibuliger* has been given. This organism has received quite intensive study by Guilliermond, Lindner, and others. It is known to form typical white-chalky colonies on various media. Saito¹⁰⁷ also found the species on bread. The defect is not common.

Red Bread. This defect is due to the growth on bread of organisms forming a red pigment, chief among which *Serratia marcescens* (*Bacillus prodigiosus*) is known. The appearance of red bread caused consternation among early people. The formation of a deep shell-pink color in bread in eastern Ontario was attributed by Reed¹⁰⁸ to bakery infection with *Monilia sitophila*.

MOLD ON BREAD AND BAKERY PRODUCTS

This is a significant bread defect, especially in warm humid weather. Pirrie¹⁰⁹ stated that 100 million loaves of bread a year are not saleable because of mold. This is a vast amount of wasted food. Bread is not the only bakery product which becomes moldy. Pirrie believed that losses owing to mold in bakery products are serious. Those who tend to belittle this problem are either uninformed or indifferent to the great loss of good food.

A general discussion of the bread-mold problem was published by Skovholt¹¹⁰ and Glabau.¹¹¹ This latter author has reviewed the more general aspects of the problem.

The baker, himself, has also contributed to his mold problems by wrapping the loaves and by slicing them. The former maintains the moisture content of the loaf at a concentration favorable to mold development while the slicing machine helps to spread mold spores over bread surfaces. The saws distribute mold spores from the surface of the loaf over fresh-cut surfaces. Therefore, sliced bread has been observed to mold more than unsliced bread in the loaf.

Moldy bread was studied as early as 1885 by Smith¹¹² who isolated several species of common molds as its cause. Welte¹¹³ also isolated *Rhizopus nigricans*, *Aspergillus nidulans*, and *Penicillium glaucum*. Herter and Fornet,¹¹⁴ who isolated and described nine species, believed that the conidia were in the flour and gained entrance to the bread in this manner. Moisture was one of the determining factors in the development of molds on bread. It is very doubtful whether molds in bread are harmful to the health of those who consume it. Brocq-Rousseau, Forgeot, and Urbain¹¹⁵ isolated a number of fungi from moldy bread, but could not prove that they were pathogenic. Prescott, Streider, and McClellan¹¹⁶ believed that the incidence of mold on bread was proportional to the sanitation of the bakery. When better sanitary procedures were introduced, moldy bread was checked. Infection of the loaf was said to take place after the loaf left the oven. *Rhizopus*, *Penicillium*, and *Aspergillus* species were especially abundant. Frazier¹¹⁷ in agreement with Herter and Fornet, believed that the flour was the source of the mold spores. He studied two flours used in the making of bread which became moldy, both of which had many mold spores. Discontinuance of these flours caused no further trouble. Wrapping caused more mold because moisture was retained, which in turn allowed the spores to germinate.

Various species of molds will develop on bread as many have shown. Herter and Fornet¹¹⁴ described 11 species belonging to the genera *Asper-*

gillus, *Penicillium*, *Mucor*, and *Rhizopus*. After baking, development of these molds in bread is influenced by various factors. One of the most important is humidity, studied by Skovholt and Bailey.¹¹⁸ Relative humidities of 80 per cent or more in air are required for appreciable mold growth on bread crust within the usual interval of time between production and consumption. Introduction of milk solids into bread increased slightly its hygroscopicity. Attempts to use carbon dioxide in control of molds on bread yielded results of no practical value.

Moldy bread is a greater problem during warm and humid seasons. While the temperature relations of all species of molds are not identical, most of them grow more rapidly at higher temperatures.

Origin of Mold Spores in Bread. Published reports indicate that mold spores may be present in materials from which bread is made or come from utensils and air in the bakery. The latter is undoubtedly one of the main sources of mold. All air is more or less laden with various microorganisms or their spores. City air is probably much more heavily laden than is country air. Since this subject is discussed more fully in another chapter in this book, it will not be discussed here. Mold spores may be brought into the bakeshop in various ways, on the street clothes of workers, on baskets and crates in which bread is handled, and by drafts of air from the outside. Mold infection is a difficulty which develops after the bread has left the oven.

Bread probably collects its load of mold spores on the cooling racks and in the wrapping machines. Both of these are exposed to the air. Wrapping and slicing of bread have contributed greatly to the mold problem even though they are considered marked advances in other ways. The former has retained moisture so important in mold growth, while the saws on the slicing machine distributed molds throughout the crumb.

Flour in some cases has been a fertile source of mold spores. Frazier¹¹⁷ studied one outbreak of moldy bread in which the flour contained as many as 11,000 mold spores per gram. When use of this flour was discontinued, the trouble stopped. The bread made from this flour showed mold in the loaf within one and one-half and two hours after leaving the oven. By the time it reached the consumer, the whole loaf was moldy.

Effect of Baking Temperatures on Mold Spores. Mold spores are not especially resistant to heat, as indicated in various places in this book. They are killed by temperatures much lower than those used in baking. Morison¹¹⁹ reported that conidia and ascospores of *Monilia* species isolated from moldy bread survived heating for 30 minutes at 50°C.(122°F.) but were destroyed by heating at 60°C.(140°F.) for 20 minutes or at 70°C.(158°F.) for 10 minutes. Loaves baked from infected dough for 30 minutes at 220°C.(428°F.) showed no evidence of mold development after five days' incubation. The work of Prescott, Strider, and McClellan¹¹⁶ would also suggest that microorganisms are killed in the loaf by baking because the center of the loaf reached a temperature of 97°C.(206.6°F.) which

118. Skovholt and Bailey. 1933. *Cereal Chem.*, 10, 446-451.

119. Morison. 1933. *Cereal Chem.*, 10, 462.

would destroy microorganisms. Brouilett¹²⁰ believed that mold spores are killed in baking and quoted Skovhold and Bailey to the same effect. While this may be generally the case, some conditions might exist which would allow them to survive. Frazier's work would indicate this.

Control of Mold on Bread. Control of molds on bread involves elimination of their spores in flour and other materials or control of them in the bread. It also involves elimination in the bakery. The problem is not simple but involves several possible methods of attack. Improvements in general sanitation of the bakery were suggested by some of the earlier authors, and while this has helped to reduce mold trouble, it has not entirely solved the problem. Related to these efforts is attainment of bacteriological cleanliness which means much more than ordinary cleanliness. Machines must be scrubbed and washed and walls and floors thoroughly cleaned. Germicidal paints are being tried on the former with some success.

Vacuum cooling of baked goods has been given considerable importance as one possible method of protecting them from undesirable organisms. The bread is cooled partially at room temperature after which it is subjected to a vacuum of from 28 to 29 inches.

The modern methods of air-conditioning also play a role in protecting bread from mold spores. Air is washed and changed so that foreign matter is continually being removed.

The mold problem has been so troublesome that various types of methods have been attempted to combat it. These have involved, in addition to those just mentioned, ozonizing the air, passing the baked goods through fungicidal vapors, and use of so-called inhibitors of which quite a few have been proposed.

A more recent attempt to control bread mold has involved use of rays from the quartz lamp. This proposal is in keeping with the efforts which have been made in practically every part of the food industry, to control microorganisms. Owen¹²¹ found that the exposure of the bread-slicing unit to ultraviolet light during slicing operations greatly reduced development of molds. These rays sterilized the saws and inactivated mold spores. Read¹²² exposed freshly baked bread heavily infected with the mature spores of the more common species of *Aspergillus*, *Penicillium*, *Rizopus*, and *Mucor* for varying lengths of time at a given distance to ultraviolet radiations from three types of mercury vapor lamps and from the open C₄ type of carbon lamp with carbons of different materials in the core. Some doubt may exist with respect to the practicability of this method for controlling "rope" in bread because of the relatively long exposure times required. They are not only expensive but might cause undesirable changes in the bread.

The carbon lamp gave better results than the mercury vapor lamp, and there was considerable variation in the effectiveness of the different car-

bons. The most effective destroyed heavy spore infection on the surface of the loaves in 45 seconds at a distance of eight inches with the lamp operated by the direct current at 75 and 60 volts. Wrapping the infected loaves in transparent sheeting, such as cellophane and Sylphwrap, did not decrease the fungicidal potency of the radiation. This process of sterilization is being used on a limited commercial scale to prevent the occurrence of mold on certain special breads. While exposure of bread to ultraviolet rays may reduce the number of viable microorganisms, it does not remove all of them. This is probably due to the fact that the rays have little if any penetrating power, as well as to the unevenness of the surface of the loaf.

The chemical substances which have been proposed at various times are added to the dough and are, in general, known as inhibitors. The most important of these are certain harmless organic acids, acetic and propionic, or their salts.

Acids have also been used for controlling development of molds on bread. Kirby, Atkin, and Frey,¹²³ using five different species of molds, observed that the effect of acidity on growth must be considered not only from the standpoint of hydrogen-ion concentration but the specific effect of the kind of acid used. At the same pH different acids varied in their effect. Fatty acids were much more toxic than mineral acids and such organic acids as lactic, citric, tartaric, and maleic. Molds, like yeasts, have a wide growth optimum with respect to pH. They seem to grow well at all pH values at which commercial bread is produced. Kirby, Atkin, and Frey believed that if a baker increases the pH of his bread to approximately 5.0 for the purpose of controlling rope, he will not increase his mold problem. If he uses acetic acid or other fatty acids of this series he would not only control rope but would also retard development of molds. A film of dilute acetic acid such as vinegar covering the surface of the loaf of bread was said to be very effective in preventing development of mold.

Mold Inhibitors in Bread. These are substances which are added to the product to repress development of mold spores which have survived baking or have reached the product after baking. Glabe¹²⁴ has stated that a good mold inhibitor must be potent in low concentrations, must be nonpoisonous to man, must not decompose in baked products, must not produce deleterious results during baking, and must have no effect on taste and odor. Such requirements restrict the chemical substances which may be used to a few. Sodium and calcium propionates have had wide use under the name Mycoban. More recently sodium diacetate (Badex) has been proposed.

Propionic acid as such, or its calcium or sodium salt, has also been proposed as a mold preventative in bread. Little doubt exists as to its retarding effect on development of molds of these compounds. Macy¹²⁵ reported prevention of mold development in butter by wrapping in parchment treated with sodium or calcium propionate. Miller¹²⁶ reported the

same results with cheese treated with solutions of propionic acid. Mold growth was not entirely eliminated but was greatly retarded. These results were supported by those from experiments by Irvine and Sproule.¹²⁷ Both of these investigations indicated marked action of calcium propionate on molds in cheese. This was confirmed for bread by O'Leary and Kralovec.¹²⁸

Is Moldy Bread Hazardous to Health? The answer is unquestionably "no." Mold spores are widespread in nature and are eaten in large numbers. No evidence has ever been produced to dispute this fact. Herter and Fornet,¹¹⁴ after an extensive investigation of the molds from moldy bread, stated that such bread was harmless. Owing to the musty flavor and appearance, it would ordinarily be excluded from the diet.

Bacteriology of Bread. Even though bread is baked in hot ovens, it is not necessarily sterile. Probably the better heated and controlled ovens of the present day are turning out bread which is more satisfactory bacteriologically than ever before. A careful bacteriological study of various breads sold today is needed to determine whether results which have been reported in the literature still represent the situation. As early as 1894, Lawrence-Hamilton¹²⁹ recognized the need for technical control in the baking industry. He studied the temperatures attained in the interior of the loaf and found that they were considerably below the temperatures of the ovens. Belli¹³⁰ and Marchand found living bacteria in bread, the number being proportional, in general, to the size of the loaf. The size of the loaf would influence the efficiency of heat penetration.

Investigators in foreign countries have studied the possibilities of pathogenic bacteria surviving the baking process. Roussel,¹³¹ Auché,¹³² Fenyvessy and Denies¹³³ and Gaujoux¹³⁴ all studied the effect of baking on *Mycobacterium tuberculosis* in dough. All of the evidence seemed to indicate that the organism was destroyed. Auché used a number of other pathogenic bacteria, finding that they were also destroyed.

Wrapping bread is a practice with considerable hygienic value. Jacobs, LeClerc, and Mason¹³⁵ and Howell¹³⁶ reported that the bacterial content of bread was determined largely by the conditions under which it was produced, and wrapping.

Considerable attention to bread hygiene still seems to be necessary in France, according to papers by Violle¹³⁷, Fouassier¹³⁸ and Aubertin, Daugoumeau, Leuret, and Piechaud.¹³⁹

While properly baked bread will probably be free from pathogenic bacteria, the danger of dissemination of pathogenic bacteria is always

present. The American practice of wrapping each loaf of bread was considered by Fouassier to be impracticable on account of the large size of French loaves. The introduction of breadmaking machinery has greatly reduced the possibility of infection from those who kneaded the bread by hand. It is quite generally agreed that maintenance of a temperature of 100-102°C. (212-215.6°F.) for at least 10 minutes, should be adequate to destroy pathogenic bacteria. La Rosa,¹⁴⁰ however, stated that same pathogenic bacteria might survive baking. Whether this would be the case depends largely on temperatures attained in the loaf during baking. On this question, results of experiments by Stout and Drosten¹⁴¹ may be quoted.

The time-temperature curves showed in all cases three general periods. During the first 10 minutes there was a rapid rise of temperature within the loaf which was more marked in the ovens of high than low temperature. This was followed by another 10 minutes in which the temperature rose at a slower rate, and finally there was a period of from nine to 12 minutes of constant temperature. The two extremes of oven temperature did not produce good loaves. In no case did the temperature within the loaf exceed 100 or 101°C. Under the experimental conditions this temperature must have been maintained for at least a period of nine minutes to produce a loaf of satisfactory doneness.

Relation of Bread to Illness. In America bread has not been incriminated in many outbreaks of illness. The nature of bread would indicate that it may be infected when handled by a carrier just as are other foods. Hansen¹⁴² reported an outbreak of typhoid fever which was believed to have been caused by bread. The evidence is not as convincing as one would desire. Louste and Godlewski¹⁴³ made a similar report for an outbreak of dysentery involving 31 cases and six deaths. When medical officers enforced rules of hygiene, the outbreak terminated. Silberschmidt also gave evidence that bread may carry pathogenic bacteria. In experiments by Alves¹⁴⁴ bread was contaminated after baking with *Eberthella typhosa*, *Shigella dysenteriae*, Shiga, and Flexner. These organisms were recoverable by cultural methods at periods varying from two to 30 hours after contamination.

Clostridium botulinum in Bread. Few experiments have been carried out with organisms in bread. Edmondson, Thom, and Giltner¹⁴⁵ inoculated enough bread dough with toxin-free spores of *Clostridium botulinum* to make one loaf. This was put through the usual procedures and finally baked in an oven held at 220°C. (428°F.) for 35 minutes. Another loaf was inoculated just after it had been worked and before being placed in the pan for the second rising. This second loaf was baked as was the former. *Clostridium botulinum* could not be recovered. One would not

expect the spores of *Clostridium botulinum* to be destroyed by the temperatures attained in bread during baking.

Yeast Foods in Breadmaking. While the materials used for making bread are sufficient to permit good growth and fermentation by the yeast, better results are secured when certain inorganic salts are added. Addition of phosphates greatly stimulates gas formation in dough and Vandevelde and Masson¹⁴⁶ observed improved results by the use of salt mixtures. The subject has been studied at considerable length in recent years in America by Kohman¹⁴⁷ and his colleagues and Hoffman.¹⁴⁸ Kohman's work apparently had its origin in the effect of different natural waters on fermentation in dough as noticed by a large baking company. He showed that the use of small quantities of ammonium and calcium salts and potassium bromide brought about a saving of 50 to 65 per cent in the amount of yeast required. Hoffman also showed the benefits of using ammonium chloride. The result of these investigations was the appearance on the market of Arkady Yeast Food," a product said to contain calcium sulfate 25, ammonium chloride 9.7, potassium bromate .3, sodium chloride 25, and patent wheat flour 40 parts. Street¹⁴⁹ confirmed the experiences of those quoted above. He was able to see no objection to the addition of the material to bread. Other studies on these products were reported by Elion¹⁵⁰ and Masters and Maughan,¹⁵¹ although their products were not of such importance in breadmaking as those discussed above.

Macaroni. This is such a dry product that microbial spoilage is rare. Occasional purple streaks on macaroni, as reported by Falkova and Mishutin,¹⁵² were due to a member of the genus *Monilia*. It was not pathogenic; the spores found in the paper wrappers were destroyed in 40 minutes at 100°C.(212°F.); older colonies were destroyed in 60 minutes at 160°C.(320°F.).

CHAPTER 18

FERMENTED FOODS

Foods are fermented for various reasons. Preservation and improvement of flavor are the main ones. Vegetables, such as cabbages, cucumbers, and even lettuce, have been preserved by fermentation for many decades. Although flavor is changed, differences of opinion might exist as to whether it is actually improved. The products of fermentation are usually acids which inhibit microorganisms that are food destroyers. In some cases these acids exert a selective action. Cream is fermented (ripened) in order to stabilize and improve the flavor. Butter made from ripened cream keeps well.

VINEGAR

Vinegar is one of the oldest fermentation products used by man. One of the first substrates fermented to yield vinegar was wine. Our modern word for vinegar comes from the two French words for sour wine, *vin-aigre*. Luckow,¹ who discussed the earlier history of the vinegar fermentation, showed how closely studies on this fermentation were associated with early advances in the study of microbiology. Pasteur's contributions were among the first to throw light on the foundations of the fermentation. He showed that living microorganisms were important. Hansen's² publication, *Recherches sur les Bacteries Acetifiantes*, was the first modern publication on the subject. In some of his pioneer work he showed that oxidation of alcohol to acetic acid was not carried out by one species but that several, to two of which he gave the names *Mycoderma aceti* and *Mycoderma pasteurianum*, were involved. These names were later changed to *Bacterium aceti* and *Bacterium pasteurianum*, and still later to names given below.

Fermentation vinegar is more than a solution of acetic acid or other organic acids. In addition, there are substances which contribute to odor, flavor, and color. The amount of acetic acid in market vinegar is prescribed by law.

In the remote past, very little attention was given to the preparation of the apples from which the juice was pressed. No serious attempt was made to sort defective fruit, nor were the apples washed. Under such conditions, the juice was not only of poor quality, but contained a rich flora of undesirable microorganisms. Vaton³ stated that in Germany, Switzerland, and some other countries it is the custom to wash the apples used for the manufacture of vinegar, but that in France opinion is divided on the matter. Vaton subjected cider apples of different kinds to a washing process, to ascertain the nature and amount of the matters removed. Twenty kilos of each kind were employed. The impurities formed a nauseous mass containing dry matter ranging in amount from two to 26 grams. The aver-

3. Vaton. 1922. L'Alimentation Modern, July, 1922.

age amount was 7.258 grams, consisting of sugar, tannin, pectic and protein materials, and ash. The loss of sugar by washing, per metric ton of apples, would scarcely amount to 281 grams, a negligible quantity. If washing is prolonged, the loss becomes greater. It is advisable, therefore, not to leave the apples for too long a time in the water and not to subject them to excessive movement. Apples should be dried after washing. The necessary operations can be carried out by means of machines, which should be found in every well-equipped cider mill. Vandecaveye⁴ stated that washing and sorting of the apples had little effect on the fermentations. This would seem to indicate that not all undesirable organisms were removed by washing. It was stated, however, that too much emphasis could not be placed on clean utensils. Certainly, clean fruit would have some advantage.

Alcoholic Fermentation. The fermentation of saccharine substances to vinegar involves two fermentations, alcoholic and acetic. The former is brought about by yeasts which are known to be widely distributed in nature and would, therefore, be present on the surface of fruits, the juices of which would constitute the substrate. The time required to complete the alcoholic fermentation depends on such conditions as temperature, composition of the juice, vigor of the yeast, air supply, etc. The most favorable temperature is about 30°C. (86°F.). The substrate should be protected from dirt and insects.

Less work has been done on the use of pure cultures of yeasts in the vinegar industry than in some of the other industrial fermentations. Perhaps it has not been needed, but it is quite probable that pure cultures would improve the product.

Acetic Acid Fermentation. The acetic acid fermentation follows the alcoholic and yields the vinegar. This oxidation of alcohol to vinegar seems to be a reaction carried on especially by the acetic bacteria. Since the making of vinegar is a process carried on by microorganisms, every attempt is made to furnish them with optimum conditions for working. The temperature limits for maximum vinegar formation seem to be 20-35.5°C. (68-96°F.). Beyond these limits, the reaction is slow. The substrate must not contain over 15 per cent of alcohol, while from 11 to 13 per cent allows greatest growth of the vinegar bacteria. On the other hand, a content of alcohol which is too low does not allow good development of the acetic bacteria. The chemistry of the acetic acid fermentation has been found to be just as complicated as the chemistry of alcoholic fermentation.

The chemical oxidation of alcohol in the presence of platinum black was first observed by Edmund Davy in 1821. This caused the early workers to believe that the reactions in the quick vinegar process occurred in the same manner. In 1864, Pasteur⁵ proved that the real promoters of this change were organisms, which grew in a delicate film over the surface of the beech shavings used in the process.

Neuberg and Windisch⁶ and his colleagues have done much to explain the chemical mechanism of the acetic acid fermentation. It is generally

4. Vandecaveye. 1926. Wash. Agr. Expt. Sta. Bull.

5. Pasteur. 1864. Ann. de l'École Normal. Suppl. 1.

6. Neuberg and Windisch. 1925. Biochem. Ztschr. 166, 454.

admitted that the oxidation of ethyl alcohol to acetic acid takes place in two stages, the oxidation of ethyl alcohol to acetaldehyde and the oxidation of the latter to acetic acid. Using Neuberg and Nord's method of fixation, which was so successful in the alcoholic fermentation, Neuberg and Windisch⁶ showed that acetic acid bacteria as well as a few others could act on the acetaldehyde, transforming it into equimolecular proportions of acetic acid and ethyl alcohol. This transformation took place in the absence of air, as well as in the presence of air. If it were merely a simple oxidation of acetaldehyde, it would only take place in presence of air. According to Neuberg's conceptions the acetaldehyde formed by oxidation of ethyl alcohol is transformed not by a direct oxidation, but by a process of "dis-mutation," into acetic acid and alcohol by a Canizzaro reaction; for each two molecules of aldehyde which enter the reaction, one is transformed by oxidation to acetic acid, while the other goes by reduction to ethyl alcohol. Identical results were secured with *Acetobacter ascendens*, *Acetobacter pasteurianus*, and *Acetobacter xylinum*. Myrback, von Buler, and Sandberg⁷ examined the acetic acid bacteria and found that they dismute acetaldehyde rapidly, and that this property was destroyed by boiling. The heated extract contained a cozymase which activated fermentation by cozymase-free yeast. Kluyver and Donker⁸ also presented a scheme to show how ethyl alcohol might be formed.

The bacteria which change ethyl alcohol to acetic acid belong to the genus *Acetobacter*. Their action is influenced greatly by other micro-organisms which may be present, according to Vaughn.⁹ The type of yeast is important.

METHODS OF MAKING VINEGAR

While the chemistry and bacteriology of vinegar making is the same, several different methods have been developed to bring about those changes.

Orleans Method. Vinegar was made in Orleans, France, by mixing vinegar with wine in tanks. As the fermentation progressed, the surface of the liquid was covered with a pellicle composed of fermenting organisms. These grew in contact with air using oxygen for oxidizing alcohol to acid. When acetic acid had reached a concentration of between 12 and 14 per cent, the fermentation stopped only to be renewed by some process which will remove the acid. Usually more wine is added after the volume of the solution has been decreased. This process unless carefully done will disturb the pellicle over the surface and therefore upset the system for a time. To obviate this difficulty, a board covering is now used upon which the "mother of vinegar" is supported in such a manner that it is not destroyed when the tank is regenerated with new wine. Sour wine with not over 10 per cent of alcohol is used. When it contains more than 10 per cent, it must be diluted with weaker wine.

Domestic Method. The generator in this method consists of a tight barrel with a capacity of 190 liters more or less. The raw material may be

7. Myrback *et al.* 1928. *Ztschr. f. Physiol. Chem.*, 175, 316-320.

8. Kluyver and Donker. 1924. *Verlags. Akad. Wetenschappen Amsterdam* 33, 895-914.

9. Vaughn. 1938. *J. Bact.* 36, 337-357.

wine, but in America it is usually fresh apple juice. The cask is partly filled so there is air space to allow good oxidation.

Quick Vinegar Process. In this process every possibility for furthering oxidation of the alcohol is sought. The alcohol containing liquid is allowed to flow slowly in a thin layer over a stratum on which are *Acetobacter*. The bacteria oxidize the alcohol to acid. The contrivance used for this purpose is called a "generator." This generator is analogous in many ways to a furnace because in both a strong oxidation is going on. The generator is an upright wooden tank from three to four feet in diameter and eight to 10 feet high. A false bottom exists about 10 inches from the base on which is placed porous material, such as beech wood shavings, corn cobs, etc., until the generator is nearly full. At the top of the generator is a tilting device which discharges the alcoholized material in either direction. As it flows through the generator *Acetobacter* oxidize the alcohol. Wüstenfeld¹⁰ found that acetification began rather promptly in the upper layers and reached its highest rate in the lower layers.

A new generator must be gotten in shape by acidulating the shavings (or other material) and establishing a rich flora of *Acetobacter*. During operation the effluent must be analyzed for acid and alcohol and the temperature carefully kept under control. If it is allowed to become too high, the bacteria may be killed. Analytical data on such vinegar were published by Hartman and Tolman.¹¹ When *Acetobacter* in a vinegar generator are harmed and fail to act normally, they are said to be "poisoned." Popper¹² studied such cases. In one, he found that failure to acetify was due to an asphalt paint used for dressing the walls. He advised against the use in or around generators of any agent which would harm the bacteria.

Since oxidation of alcohol in making vinegar has much in common with the aeration method of treating sewage, Fowler and Subramaniam¹³ were interested to determine whether increased oxidation of alcohol would result from forcing air through the substrate. Good oxidation resulted, although strict attention had to be given to amount of air which was used. They could observe no benefits from presence of "activated silt." The method seems to be worthy of more study.

Various Types of Vinegar. Almost any substrate which contains sufficient sugar and nitrogenous food materials may be fermented to acetic acid. Besides those mentioned in the early paragraphs in this section, several others may be briefly discussed here. Chace and Poore¹⁴ described orange vinegar in a study of possible uses for citrus by-products. A generator was described. Poore¹⁵ described a method for making orange vinegar in the home without a generator. Fabian¹⁶ published formulas for making vinegar from honey. According to Hofmann,¹⁷ honey vinegar has been made

in Holland on a commercial scale for a long time. According to Von Loesecke,¹⁸ bananas may be used, and Pernot¹⁹ suggested prunes as a fermentable substrate. Vinegars made from these materials would possess flavors and aromas somewhat different from apple vinegar, but would probably be just as satisfactory. Low-grade honey was used for vinegar manufacture by Fabian.¹⁶ A satisfactory formula consisted of from 40 to 45 pounds of extracted honey, 30 gallons of water, two ounces of potassium tartrate, and two ounces ammonium phosphate. The solution was sterilized and pitched with yeast for the alcoholic fermentation. When this was finished it was inoculated with *Acetobacter* for the acetic fermentation. Bhagwan and Sarin²⁰ used dates as raw material for vinegar making. The fruit was cooked and the juice pressed out for fermentation.

Microbiology of Vinegar Manufacture. The microbiology of vinegar has received much study. Some of the earliest investigators in microbiology studied it and secured data which in light of present knowledge and information, are quite accurate. Persoon in 1822 recognized the plant nature of some of the fungi concerned in acetic acid fermentation. Pasteur⁵ proved that acetic acid resulted from development of microorganisms, and not from chemical reactions alone. Hansen reported isolation of several acetic acid bacteria to which he gave the names, *Bacterium pasteurianum*, *Bacterium Kützingianum*, and *Bacterium aceti*. He classed Pasteur's *Mycoderma aceti*, and *Bacterium aceti* with *Bacterium pasteurianum* and *Bacterium kützingianum*. Later on, Brown²¹ isolated a new organism to which he gave the name *Bacterium xylinum*.

Identification of acetic acid bacteria is complicated by the fact that many names appear in the literature of the subject for the same species. Bergey's *Manual of Determinative Bacteriology*, Fifth Edition, lists 15 species in the genus *Acetobacter*. Five more species are listed as probable members of the genus. Henneberg,²² Rothenbach,²³ Hoyer,²⁴ Mason,²⁵ and Beijerinck²⁶ attempted to systematize the group. Henneberg²⁷ recognized two groups of vinegar bacteria, "culture" and "wild." *Bacillus orleanse* belonged to the first group as did *Bacillus xylinoides*. To the second group belonged *Acetobacter xylinum*, *Bacillus vini acetate*, and *Acetobacter ascendens*. These bacteria were said to be characterized by type of films formed on media. The so-called "culture" acetic acid bacteria (*Bacillus xylinoides* and *Bacillus orleanse*) and the "wild" species *Acetobacter ascendens* (*Bacillus ascendens*) were reported to develop in as much as 10 to 12 per cent of alcohol. Henneberg stated that acetic acid bacteria which had not been grown in wine vinegar would have to be acclimated to the high acetic

acid and alcohol content of the substrate. Inoculation should be effected in such a manner that the film particles float on the surface of the liquid.

The acetic acid bacteria are very pleomorphic. They grow on the surface of suitable media with a film of pellicle. The cells of this film are held together by a mucilaginous substance equivalent to, if not a true, capsular material. This constitutes the so-called "mother-of-vinegar." Perold²⁸ stated that involution forms usually appeared under undesirable conditions, but that this was not always the case. He even stated that they were of service in identification of cultures.

According to Grove,²⁹ who examined from 30 to 40 acetified ciders, *Acetobacter xylinum* is the most common species. Acetification abilities of several cultures which were isolated differed considerably and was markedly affected by temperature. It was much slower at 15°C.(59°F.) than at 25°C.(77°F.).

The oxidizing ability of *Acetobacter*, according to Mezzadrolì³⁰ may deteriorate and even become nil. When propagated on unsuitable media, they became more pleomorphic and lost their ability to acetify. He recommended Pasteur's medium as useful for maintaining cultures. *Acetobacter* seem to be just as resistant to unfavorable conditions as other bacteria. For instance, Hansen³¹ reported that they continued to exist for over nine years in lager beer, five to six in "double" beer, and two years in sucrose solution. They died in 16 months in water. Therefore, Hansen suggested keeping them in lager beer. In an earlier paper Hansen^{2, 31} had shown that dry storage of *Acetobacter* showed greater longevity. Sealed in glass tubes and stored at 2°C.(35.6°F.) the cells survived for more than a year. Beijerinck²⁶ stated that this method of storage might influence the activity of such organisms.

Pure Cultures in Vinegar Fermentation. Pure cultures have not been used in the vinegar industry to the same extent as in other industries. It has been shown however, that they are helpful, although there are many conflicting conclusions. Henneberg,²⁷ using pure cultures of acetic acid bacteria, was able to secure a clear product with 11½ per cent of acetic acid. He was convinced that undesirable bacteria could be suppressed with pure cultures and a better bouquet developed. Cruess³² stated that some manufacturers in California prepare a starter by inoculating fresh juice with pressed yeast. This is used in turn to inoculate larger batches of juice. Small-scale studies by Cruess and his collaborators showed that good results were obtained by using pure cultures of yeast in vinegar making. Cruess believed that the wild yeasts could be overgrown by a culture of selected yeast with a consequent increase in alcohol production. Grove,³³ who used pure cultures to secure a more regular and cleaner fermentation and perhaps an improvement in the flavor and aroma, believed that sterile sub-

strate should be used. Satisfactory methods, however, for securing sterile juice are difficult to secure for large-scale production. Although the flavor might be affected, Grove proposed heating the substrate. Ultraviolet light was also suggested, but this would probably not be effective on highly colored juices. He found little difference in the rate of fermentation of inoculated juices and those allowed to ferment naturally. Similar results were reported by Tanner and Vogele.³⁴ On the other hand, Mezzadrolì³⁵ and Vandecaveye⁴ reported favorable results after the use of pure cultures. The few conflicting data may be explained by the fact that personal equation might enter in determining whether vinegars were improved by inoculation or not.

Bottling of Vinegar. Complete fermentation may yield a vinegar which is stable. However, if it is not completely fermented, trouble may result from slow fermentations which may continue when the vinegar is bottled. Therefore, the bottles are often pasteurized at temperatures around 68.3°C. (155°F.). This ought to kill the organisms which are directly concerned in vinegar fermentation.

DEFECTS OF VINEGAR

Besides the usual defects, such as low-acid content and abnormal flavor and color, vinegar is subject to other spoilage.

Vinegar Eels. These are small forms of animal life which live in the finished vinegar. They also exist in fermenting vinegar where they interfere with acetification. Paserini³⁵ observed better "mother" formation where no eels were present. Where eels were present the mother settled, bringing about a decomposition of acetic acid. Sacher³⁶ reported that heating to 45°C. (113°F.) for a few minutes killed the organism. Sunlight also killed them but its use was unsatisfactory if further action of *Acetobacter* was desired.

Loss of Acid. Any organism which can decompose acetic acid may cause a loss of acid. Janke³⁷ reported that algae (*Prototheca* sp.) brought about such an oxidation. Wüstenfeld³⁸ found that the algae could be destroyed by ultraviolet light and a temperature of 30°C. (86°F.).

Black Vinegar. This is due to iron and tannin in proper ratios. The usual source of iron in vinegar according to Campbell,³⁹ is the appliances. As little as .01 per cent of iron will cause black vinegar.

Vinegar Analysis for Food Preservers. It is always necessary for those interested in food preservation to know the strength of vinegar which is being used. The chemist is able to use methods and apparatus which give accurate results. Some of them have been adapted to use by persons untrained in chemistry.

The Leo Tester. This apparatus is distributed by concerns which handle supplies for vinegar makers. Cruess⁴⁰ described its use and stated that it gave results accurate

enough for factory control. An exact volume of vinegar is measured into a bottle by means of a small marked glass tube. A pinch of baking soda (sodium bicarbonate) is added and the cork at once placed tightly in the bottle. The acid in the vinegar reacts with the soda and liberates carbon dioxide. This forces water from a second bottle upward into a vertical glass cylinder marked in grains. The first bottle is gently shaken until the water ceases to rise. The reading is in grains. A good cider vinegar must test at least 40 grains; distilled vinegar 85 to 110 grains.

Titration Method. Measure 10 ml. of the vinegar into an Erlenmeyer flask, add 50 ml. of distilled water and titrate with normal sodium hydroxide with phenolphthalein as the indicator. Titrate to a red color. To determine the per cent of acid multiply the burette reading by .6 when sodium hydroxide is used. If desired, the sodium hydroxide may be tenth normal, in which case the vinegar should also be diluted in a volumetric flask. Place 10 ml. of vinegar in a volumetric flask and dilute to the mark with distilled water.

Rysavy and Hac⁴¹ described a special pipette which delivered 18.012 ml. of vinegar; when titrated with normal sodium hydroxide, the reading on the burette was in per cent.

Preserving Action of Vinegar. The preserving action of vinegar as such is probably of little practical importance. While it may delay the appearance of molds it is apparently of only incidental value. It probably has some value when used with other substances. Bitting⁴² reached this conclusion after studying its preserving action in catsup. He apparently used commercial distilled vinegar and not cider vinegar made from apple juice. When 30 per cent of 50-grain distilled vinegar was added to tomato bouillon, mold development was checked and the extent to which it was checked increased with increased amounts of vinegar. In this concentration development was delayed two days. One-half of one per cent solution of glacial acetic acid in tomato bouillon accomplished what 30 per cent vinegar did; no development occurred when the quantity of one per cent solution of glacial acetic acid was increased to two per cent. Bitting observed that with increased amounts of vinegar in the tomato bouillon, more sugar and spice had to be added to overcome the pungency of the acid and insure good flavor. More recent investigations by Levine and Fellers⁴³ indicated that bacteria could not grow in bouillon adjusted to pH 4.9 with acetic acid. *Saccharomyces cerevisiae* did not grow at pH 3.9 and *Aspergillus niger* was inhibited at pH 4.1. Thermal death times of bacteria were decreased by presence of acetic acid while they were not altered for yeasts and molds. Levine and Fellers apparently based their thinking mainly on pH. That other factors may be involved was suggested by Ash.⁴⁴ He suggested that the acetate radical might be more important than what pH produced. The preservative effect of .75 per cent of acetic acid was said to be equal to .1 per cent of sodium benzoate.

In addition to the factors mentioned above others which are present in vinegar may exert an inhibitive action on microorganisms. Vinegar is known to contain propionic acid which has been shown to inhibit development of molds. This might explain the inhibitive action of vinegar for preventing development of mold in bread.

SAUERKRAUT

In Food Inspection Decision 196, August 1925, the following definition and standard for sauerkraut as adopted by the Joint Committee on Definitions and Standards, composed of representatives of the United States Department of Agriculture, the Association of American Dairy, Food and Drug Officials, and the Association of Official Agricultural Chemists, at its meeting July 13 to 17, 1925, was reported:

Sauerkraut is the clean, sound product, of characteristic acid flavor obtained by the full fermentation, chiefly lactic, of properly prepared and shredded cabbage in the presence of not less than two per cent (2%) nor more than three per cent (3%) of salt.

It contains, upon completion of the fermentation, not less than one and one-half per cent (1.5%) of acid, expressed as lactic acid. Sauerkraut which has been rebrined in the process of canning or repacking contains not less than one per cent (1%) of acid, expressed as lactic acid.

Sauerkraut is prepared by salting shredded cabbage. Alternate layers of cabbage and salt are packed into containers and allowed to ferment. About three pounds of salt are used for each 100 pounds of cabbage. The salt withdraws the juice from the cabbage tissue. A brine results in which the acid-forming bacteria thrive. They ferment sugars to organic acids which act as preserving agents and prevent action of putrefactive bacteria. The fact that sauerkraut is a fermented food makes it possible to have various grades and flavors. Fred and Peterson⁴⁵ found low titratable acids and higher alcohol contents in inferior sauerkraut. Good kraut always showed numerous lactic acid bacteria with an occasional yeast cell while abnormal kraut showed different kinds of bacteria and large numbers of yeasts.

During the early fermentation of sauerkraut, large amounts of gas are given off. Preuss, Peterson, and Fred⁴⁶ found that it resulted from bacterial action and not from yeast growth or plant cell respiration. It consisted almost entirely of carbon dioxide.

The nature of the fermentation is controlled by the type of cabbage content of salt, temperature of fermentation, and activity of the ferment-started normal fermentations; sugars of cabbage were said to be converted to lactic and acetic acids, alcohol, mannitol, and carbon dioxide. The fermentation was continued and completed by certain lactobacilli, such as *Lactobacillus plantarum* and *Lactobacillus brevis*. It is, then, the sugar in the cabbage which is the source of organic acids so important in preservation of the cabbage tissue. These vary in the cabbage according to season, variety, and stage of maturity. If too little is present to permit sufficient acid to be formed, spoilage may result. Some investigators have added sugar to the cabbage in order to prevent this. Fellers, Clague, and Levine⁴⁸ added from one to two per cent of glucose or sucrose, or mixtures of these sugars, to raw vegetables before fermentation and after it had been in progress for some time. This greatly increased the number of bacteria but did not increase final acidity. However, if the sugars were added after the

48. Fellers, Clague, and Levine. 1939. Idem, p. 88.

acidity had reached one per cent, final acidity was materially increased. Fellers and his colleagues believed that added sugar might be useful in promoting rapidity of fermentation which in turn, would decrease the possibilities of spoilage owing to growth of bacteria and yeasts. High final acidities were believed to promote keeping and to have no effect on flavor.

The time required for fermenting cabbage to become sauerkraut depends on many factors. Pederson⁴⁹ showed that the lower the temperature at the time of filling the vats, the slower is the rate of fermentation. Temperature of the building also has some effect on fermentation. In view of these facts the time required for a vat of cabbage to ferment cannot be predicted. Another factor of importance is washing of the cabbage. Keipper, Peterson, Fred, and Vaughn⁵⁰ reported that it was desirable. In the laboratory 84 per cent of sauerkraut made from washed cabbage graded "good to fancy," whereas only 19 per cent of that from unwashed cabbage reached this grade. Under factory conditions, the increase in quality obtained by washing amounted to 17 to 50 per cent. Washing removed many undesirable microorganisms. Chlorine in the water was found to be undesirable because of objectionable flavors which resulted. While inoculation with pure cultures was slightly beneficial, it was not considered to be of any great practical value.

Microbiology of Sauerkraut. Since sauerkraut is a fermented product, its microbiology has been much studied. Yeasts were important in the fermentation of cabbage along with gas-forming bacteria. Wehmer⁵¹ believed that lactic acid fermentation was most significant. Besides yeasts (*Saccharomyces mycoderma* I and II) and lactic acid bacteria he found a small rod *Bacillus brassicae*. Wehmer⁵¹ believed that acid formation in kraut resulted from action of this organism. It was not well characterized but LeFevre believed it was identical with *Lactobacillus cucumeris* (*Bacterium cucumeris fermentati*) of Henneberg and *Lactobacillus pentoaceticus* of Fred, Peterson, and Davenport.⁵² Preuss, Peterson and Fred,⁵³ however, did not agree with LeFevre that *Lactobacillus pentoaceticus* and *Bacterium brassicae* were identical. Conradi⁵⁴ isolated a *Lactobacillus* sp. as the organism responsible for sauerkraut fermentation, while Henneberg⁵⁵ isolated an organism to which he gave the name *Lactobacillus fermentatae* (*Bacillus brassicae fermentatae*). Butjagin,⁵⁶ Gruber⁵⁷ and Henneberg⁵⁸ also made contributions.

In America, Round⁵⁹ believed that bacteria alone, and not yeasts, were the active fermenting agents. Respiration of plant tissue cells was also ruled out. Steamed cabbage inoculated with a known starter from another

actively fermenting tank produced no gas, while a jar of the brine and cabbage developed gas in 12 hours. Round belittled the idea that salt was essential in exact amounts. From two to three per cent of salt exerted little influence on the fermentation. He stated that the function of salt was to extract water from the cabbage; the cabbage to which water had been added instead of salt fermented as well as when salt had been added. *Escherichia coli* was found to be present in large numbers at first. When the brine reached from seven to eight per cent acidity, coliform bacteria dropped out. The organisms which produced high concentration of acid were closely related to *B. brassicae* (Wehmer) and *Lactobacillus cucumeris* (*Bacillus cucumeris fermentatae*) (Henneberg).

Various species of bacteria were also reported by Pederson⁴⁹ from examination of three normal and five inoculated krauts. *Leuconostoc mesenteroides*, *Lactobacillus pentoaceticus*, *Lactobacillus cucumeris*, and *Lactobacillus plantarum* were found to be commonly present. The first organism mentioned was reported to be largely responsible for early development of acidity. Lactobacilli were said to complete the fermentation. Acids formed in the kraut were shown to be very important by Nelson and Beck.⁶⁰ Their work indicates the error in giving lactic acid all of the credit for preservation of kraut.

Products formed during a normal fermentation and the influence of inoculation on these products and the quality were examined by Brunkow, Peterson, and Fred.⁶¹ Inoculation seemed to increase the number of bacteria. This varied from 500,000 to 91,000,000 per ml. of brine. A better product was secured by inoculation. *Lactobacillus lactis acidi* (*B. lactis acidi*) gave consistently better kraut. Large numbers of yeasts were said to cause red kraut. Two per cent salt seemed to yield the best product. Above three per cent gave a tough and salty product. The chief products were found to be lactic acid, acetic acid, and ethyl alcohol. Temperature of fermentation was reported by Martin, Peterson, Fred, and Vaughn⁶² to greatly influence the quality. The most favorable temperature was reported to be between 15.6°C. (60°F.) and 18.3°C. (65°F.). Higher temperatures favored the production of soft and pink kraut. During the first few days of fermentation, a rise of 3 to 5°F. above the temperature of the surrounding air was noticed.

Use of Pure Culture in Sauerkraut Fermentation. The fermentation of cabbage to sauerkraut is greatly influenced by the presence of certain microorganisms whether they are added or not. Since undesirable bacteria give abnormal flavors, attempts have been made to override them with cultures of desirable bacteria. The evidence on the value of such cultures does not always agree. Reference will not be made to the earlier work in Germany on this subject but only to those papers which have been published in very recent years in America. Fred and Peterson⁴⁵ believed that inoculation always yielded a better sauerkraut. Besides improved flavor and aroma,

60. Nelson and Beck. 1918. J. Amer. Chem. Soc., 40, 1001-1005.

61. Brunkow, Peterson, and Fred. 1921. J. Amer. Chem. Soc., 43, 2244-2255.

62. Martin, Peterson, Fred, and Vaughn. 1929. J. Agr. Res. 39, 285-292.

inoculated sauerkraut fermented more rapidly with a great saving of time. LeFevre⁶³ did not recommend the use of pure cultures of *Lactobacillus brassicae*. Considering the experience of the industry as well as the results of research work one is convinced that sauerkraut of good quality may be made without artificial inoculation. However, inoculation might give improved fermentation under some conditions. Such was the case in experiments conducted by Peterson, Fred, and Viljoen⁶⁴. Addition of selected pure cultures of bacteria to vats of fermenting cabbags gave superior sauerkraut. While over 80 per cent of inoculated sauerkraut had good color, only some 25 per cent of the uninoculated was in this class. Indifferent results were secured by Pederson at the New York Agricultural Experiment Station with pure culture inoculation. In his first experiments, 72 different sauerkrauts were made, all but 25 of which were inoculated with pure cultures of some one of the following bacteria: *Streptococcus lactis*, *Leuconostoc mesenteroides*, *Lactobacillus buchneri*, *Lactobacillus pentoaceticus*, *Lactobacillus delbrücki*, *Lactobacillus cucumeris*, *Lactobacillus plantarum*, and two other cultures. Normal sauerkraut completed its fermentation at 21.1 to 29.4°C. (70 to 85°F) in two to three weeks when it attained an acidity of 1.5 per cent or more. Inoculation with pure cultures of *Streptococcus lactis* improved quality and did not affect the by-products. Inoculation with *Lactobacillus brassicae*, *Lactobacillus cucumeris*, and *Lactobacillus plantarum* was detrimental to good fermentation; inoculation with *Lactobacillus pentoaceticus* resulted in sauerkraut of fair quality but abnormal in flavor. Pederson's results showed that much care must be taken in selecting the culture to be used and that it is best to attempt to duplicate the normal flora of the cabbage. Pederson also used mixed cultures of *Streptococcus lactis*, *Leuconostoc mesenteroides*, *Lactobacillus pentoaceticus*, and *Lactobacillus cucumeris*. This was said to be of doubtful value.

Sauerkraut is subject to several abnormal fermentations. These may be due to presence of undesirable bacteria in the fermentation vats or to introduction of such forms after fermentation has started. A spoilage of sauerkraut, studied by Peterson and Fred⁶⁵ was found to be due to yeasts. Deterioration followed the first fermentation and occurred after the sauerkraut had been repacked for shipment. The acids were low and allowed acid-utilizing yeasts to develop.

Pink Sauerkraut. This is a defect which practically every sauerkraut manufacturer has had to battle. The trouble is connected with uneven salting. Butjagin⁵⁶ and Wehmer⁵¹ were among the first to attribute pink kraut to the presence of microorganisms. Henneberg⁵⁸ secured pink kraut after adding 1.2 per cent of lactic acid to shredded cabbage. Fred and Peterson,⁶⁶ by chemical analysis, could observe no difference between normal and pink kraut. Bacteriological examination revealed the presence of bacteria and a yeast which formed a red pigment in the presence of air. Temperatures of 22°C. (71.6°F) and 28°C. (82.4°F.) seemed to permit greatest

growth. The deepest pigment was formed at 22°C. The yeast was able to live in high concentrations of salt and thus have a free hand in producing its pigment. Pederson and Kelly ⁶⁷ also found yeasts involved in formation of a pink color in sauerkraut. Growth of the yeasts seemed to be encouraged by over salting or any condition which interfered with normal development of the bacteria.

LeFevre's Method for Determining the Salt Content of Pickle or Sauerkraut Brine with the Salinometer (Salometer). The following instructions are taken from LeFevre's bulletin:

The salt strength of brine is determined by means of a salinometer, which should form a part of the equipment of every sauerkraut factory. The salinometer scale is graduated into 100°, which show the range of salt concentration between 0°, the reading of pure water at 15.55°C.(60°F.), and 100°, which indicates a saturated salt solution (26½ per cent). In a pure salt solution the salinometer shows accurately the percentage of salt. As sauerkraut brine, however, is not a pure salt solution but contains much other soluble material, a salinometer reading can be regarded only as a measure of its total solids. This may vary greatly in different samples, depending not only on the quantity of salt added but upon the moisture content and the soluble constituents of the cabbage. Under ordinary conditions when 2.5 per cent of salt has been added a salinometer reading of about 17° is obtained.

LeFevre's Method for Determining the Amount of Acid Formed in Pickle and Sauerkraut Brine. The following technic is taken verbatim from LeFevre's publication:

For determining the acidity of the brine in a tank of sauerkraut a small sample should be taken by suction through a glass tube. This sample should be obtained at least two feet below the surface and from the sides of the tank. Brine obtained by opening the bottom vent should not be used, as it may differ from the above and is not a representative sample. Brine from the middle of the tank would best represent the average acidity in the tank. If possible, a hole should be provided in the tank for obtaining this brine.

The acidity of sauerkraut may be determined with sufficient accuracy by titration of the brine against an alkaline solution of known strength. A normal solution of sodium hydroxide is generally used. The test gives no information regarding the kind of acid in the brine but determines only the quantity of normal alkali which is required to counteract its acidity and produce neutrality. The quantity of normal alkali used to produce neutrality multiplied by the appropriate figure for the acid gives the number of grams of acid per 100 cubic centimeters of brine. This factor for lactic acid is 0.09. Although the acid in sauerkraut is not entirely lactic, it is mainly lactic, and it is therefore calculated as lactic acid.

Grams of acid per 100 cubic centimeters of brine is not quite the same as by weight, but it is nearly the same and is often referred to as percentage.

The methods of making titrations differ slightly in detail, but any of them may be easily followed. Although not the simplest, the following method is perhaps the best.

With a pipette transfer exactly five cubic centimeters of the sample of brine to a 100-cubic centimeter Erlenmeyer flask. Add to this 45 cubic centimeters of distilled water and three or four drops of a phenolphthalein solution. Then run in slowly from a burette a one-twentieth normal solution of sodium hydroxide. While this is running shake the flask constantly and watch it carefully. As soon as a permanent faint pink tint is produced throughout the solution the neutral point has been reached and no more should be added. It is important that the addition of alkali stop at the first appearance of the pinkish tint. Read to a fraction on the burette the number of cubic centimeters required to neutralize the brine. Multiplying this number by 0.09 gives the grams of acid, calculated as lactic, in 100 cubic centimeters.

If it is desired to use a one-tenth normal sodium hydroxide solution start with 10 cubic centimeters of brine and 40 cubic centimeters of distilled water and proceed as before.

67. Pederson and Kelly. 1938: Food Research 3, 583-588.

The acidity may be tested more simply and the result may be read directly in percentage of lactic acid by the following method: Use a one-ninth normal solution of sodium hydroxide (1 part normal sodium hydroxide solution to 8 parts distilled water), place 10 cc. of brine in the flask, add 40 cc. of distilled water, and proceed as before. The number obtained divided by ten gives the percentage of lactic acid in the brine.

Microbiological Examination of Fermented Foods. Such examination is of no great importance as a routine procedure. It may be desirable at times to examine canned sauerkraut for sterility or raw sauerkraut for special microorganisms. The Committee on Microbiological Examination of Foods of the American Public Health Association recommended use of tryptone-glucose-yeast extract agar as a plating medium. The Frost little plate method described on p. 355 was also recommended.

Canned Sauerkraut. Much kraut is canned today in America. According to McConkie⁶⁸ it may undergo two types of spoilage. One, caused by bacterial activity which results in "swells" with formation of carbon dioxide and hydrogen, is due to understerilization and later development of microorganisms which have survived the process. Cannerymen have learned that more attention to acidity of the kraut before canning, to the exhaust, and to processing will yield a product which will keep well. The other type of spoilage to which canned sauerkraut is susceptible is the hydrogen springer or swell. Kraut is processed in cans for about 15 minutes at 100°C. (212°F.) for No. 2 cans and for 40 minutes at the same temperature for No. 10 cans.

Analysis of over 100 samples of sauerkraut from over 70 different packers by Pederson⁶⁹, showed that at least one-third did not conform to the regulations of the U. S. Federal Food and Drug Administration. Some was unfit for consumption, defects being pink color and unpleasant odors and flavor. The analytical methods used were determination of salt, total acid, volatile and nonvolatile acid (by difference), alcohol, and such inspection points as length of cut, texture, color, odor, and flavor. A supplemental microscope examination of the juice for yeasts was often helpful. Secondary fermentations are usually caused by yeasts. These methods and findings from them are not sufficiently worked out to enable definite standards to be set up but are advanced as valuable sorting procedures. Pederson⁶⁹ observed that good kraut was also good as far as chemical composition was concerned.

Lettuce Kraut. Attempts have been made by the California Agricultural Experiment Station⁷⁰ to use lettuce as a raw material for kraut manufacture. Natural fermentation yielded a good product although use of starters of *Lactobacillus pentosus* gave a superior flavor. In general the changes which were observed paralleled those which have been observed for cabbage kraut. Addition of dextrose to the lettuce either before or during the fermentation had little or no effect upon total acid produced. The most prevalent organisms found in lactic acid fermentations of lettuce were *Lactobacillus plantarum* (Orla-Jensen) Bergey *et al.*, and *L. brevis* (Orla-Jensen) Bergey *et al.*, and some nonsporulating, film-forming yeasts.

69. Pederson. 1934. Amer. J. Pub. Health 24, 229-234; New York Agr. Expt. Sta. (1940) Bull. 693.

70. Hohl and Cruess. 1940. Inst. Food Tech. Proc., 159-166. Hohl. 1942. Food Research 7, 309-312.

Occasional cultures of *L. buchneri* (Henneberg) Bergey *et al.* and *Leuconostoc mesenteroides* (Cienkowski) Van Tieghem were also isolated.

CUCUMBER PICKLES

Cucumber pickles are made by placing fresh cucumbers in brine until certain changes have occurred. Most of the latter result from bacterial action and everything is done to further the activity of desirable bacteria and repress that of spoilage types. Many kinds of pickles and specialties described by Fabian and Switzer⁷¹ are manufactured.

Pickles have been made for a long time in the home, but in more recent years they have been made by large manufacturers. The industry is now profiting from application of scientific methods. The methods used by large manufacturers differ somewhat from those which are used in the home. The pickle manufacturer uses fermentation to develop the chemical compounds which make the pickles keep. The homemaker would find such a method too cumbersome for small quantities of cucumbers; consequently, she tries to prevent fermentation, resorting to heat and antiseptics, such as spices and vinegar, to control bacteria. The fermentation method is probably best for the manufacturer and the sterilization method best for the home. Under the conditions which obtain in commercial manufacture of pickles, the cucumbers are brought to salting stations, where they are dumped into large tanks, often without washing or cleaning. The tanks are sometimes placed in the open, where they are exposed to dust and dirt. It is possible that cleansing of the cucumbers might be advantageous, since it would reduce to a minimum extraneous bacteria which would enter the tanks. The fewer such bacteria, the lighter would be the load on the factors involved in preservation.

In the pickle industry salt concentrations are usually not given in per cents but in degrees. Zero degrees is water and 100° is a saturated solution of salt in water, *i.e.*, 26.395 per cent. For comparison, the following data are given:

Degrees	% NaCl	Degrees	% NaCl
10	2.64	60	15.80
20	5.82	70	15.80
30	7.80	80	21.06
40	10.57	90	23.76
50	13.19	100	26.40

It is very necessary that the strength of the brine be carefully watched during fermentation. Usually a hydrometer known as a "saltometer" is used. This is graduated in degrees from 0 to 100 showing the saturation at 60°C. (140°F.). Hasbrouck⁷² has found the Baumé hydrometer satisfactory. Data for preparing a brine of any strength are given in the table.

Hasbrouck⁷² did not approve the use of the saltometer because saltometers may be too inaccurate. He advised that salting be done according

71. Fabian and Switzer. 1941. Fruit Prod. J., 20, 136-140.

72. Hasbrouck. 1910. Pure Food 6, 509-514.

to temperature. As the temperature rises the concentration of the brine should be raised, since at higher temperatures bacterial activity is accelerated.

Pounds of salt per gallon of water	Degrees on saltometer	Pounds of salt per gallon of water	Degrees on saltometer
5	0.11	55	1.42
10	0.22	60	1.57
15	0.33	65	1.72
20	0.45	70	1.89
25	0.58	75	2.07
30	0.70	80	2.24
35	0.83	85	2.42
40	0.97	90	2.60
45	1.12	95	2.78
50	1.27	100	2.98

The pickling season begins in the middle or late summer and lasts until frosts kill the vines. In the beginning and at the end of the season, when only a few cucumbers are delivered to the factory they may be put into smaller containers, while in the middle of the season they are salted in large tanks, holding 1,000 to 15,000 bushels. According to Campbell, the size of the tank may vary from eight to 14 feet while the height is usually about eight feet. If the cucumbers are to be salted in a barrel, they may be put into a 20-per cent brine (equal to 80°). In such a strong solution they will naturally float, and have to be forced under the surface by means of boards which are weighted down or nailed down. With large tanks the procedure may be a little different. The tank is started with about six inches of brine to which cucumbers and salt are added in the average proportion of five to six pounds of salt per bushel of cucumbers. The strong brine draws the water from the cucumber, which causes them to shrivel for a time, but in a day or two they are plump again. When the tank is full, enough water is added to cover the cucumbers which are pressed or "keyed down" below the surface of the brine. The cover holding them down consists of heavy boards with cracks to let the fermentation gases escape.

The manufacturer tries to fill a tank as quickly as possible. While the cucumbers are not covered with brine and exposed to air, they are apt to spoil. After the tank or barrel has been "keyed down," the fermentation starts, and very little has to be done to the cucumbers. The brine remains clear for a few days, depending on the temperature, and turns cloudy just before active fermentation begins. During this preliminary stage the brine is becoming saturated with materials taken from the cucumber. When the fermentation starts, gas bubbles arise through the cracks slowly at first, and then very rapidly. Rahn⁷³ stated that in a factory which came under his observation a large tank was filled very late in the season. A sudden change in the weather stopped fermentation. The following May, after a few warm days, fermentation started again and continued for two weeks.

73. Rahn. 1913. *The Canner and Dried Fruit Packer*, Nov. 20, p. 27.

Besides gas formation, which is a criterion of fermentation, there are other evidences that changes are taking place. The cucumber changes in color. The fresh pale green color is replaced by a darker olive green. A manufacturer can follow the progress of curing by examining a cross section of the cucumber in cure. As curing progresses, the white opaque appearance is changed from the outside toward the center to a transparent green. When the white appearance is entirely replaced, curing is complete, and the cucumber is too heavy to float. LeFevre⁷⁴ reported a marked loss in weight which was not regained for over a month.

The pickles remain in this brine until they are to be sold or manufactured into sweet, sour, dill, and other kinds. Then they are sorted according to size, whether by hand or by machine, and washed in brine or water. As long as they remain in brine, they keep very well, and occasionally a factory may hold pickles of a certain size for several years. If the tanks are not under roof, they have to be filled up after long drought and salt may have to be added after heavy rains. The brine is tested by a salometer and is ordinarily kept at 40° (10 per cent salt). Some manufacturers prevent this trouble by putting the tanks under roof, but this brings another difficulty, namely, the scum or film. On brine pickles under roof there forms invariably a heavy, gray, wrinkled scum which becomes very thick and has to be removed once in a while since, as the manufacturer says, it makes the pickles slippery if it settles. This thick scum is due to the growth of yeasts, a group of microorganisms detrimental to the pickle industry.

Salt plays a great rôle in restricting development of proteolytic bacteria which would destroy the cucumbers. Fabian, Bryan and Etchells⁷⁵ found that while at first they were more abundant than acid-producing bacteria, they were gradually killed by the brine, more rapidly in a brine of 40° salometer than in a 30° brine.

The composition of cucumbers has been determined by Heinze,⁷⁶ who showed that from the point of food value the pickle does not hold a prominent place. The cucumber in the fresh condition is composed mostly of water, about 96 per cent, and four per cent of solids. These solids seem to be mostly sugar and proteins in about equal amounts. Heinze also reported results of analyses for dill pickles.

The curing process consists mainly of an acid-gas fermentation. As much as one per cent of lactic acid has been found in the brine in some cases. The rapidity of fermentation, according to Campbell,⁷⁷ depends on the concentration of the brine. Some have attempted to secure earlier fermentations by adding a little sugar to the brine. (Aderhold.⁷⁸)

From a gaseous fermentation occurring during salting, Etchells⁷⁹ isolated some 29 strains of bacteria. Most of them were closer in characteristics to *Aerobacter cloacae* than to *Aerobacter aerogenes*. The optimum

temperature was near 35°C. (95°F.) with a possible range from 5 to 45°C. (41 to 113°F.). More gas seemed to be formed in heavier brines.

Microbiology of Brine Pickles. Fermentation of brine pickles is known to be caused by microorganisms. Bacteria are also known to cause undesirable changes such as softening, blackening, etc. When a normal fermentation has been secured the pickles will keep if the manufacturer holds them under the proper conditions.

The undesirable results of the presence of film yeasts on the surface of pickle tanks have been recognized for some time. They decompose the acid and make it possible for putrefactive bacteria to develop. Rahn,⁷³ Riley,⁸⁰ and Brown⁸¹ showed that film yeasts were acid consumers.

Despite the fact that fermentation of pickles is an old industry, much research may yet be done and must be done before it can be considered a controlled fermentation. There is great need for combined microbiological and chemical investigations. To date, most of the work has been microbiological in nature, with almost no attention to the chemical products which are formed by these microorganisms. Investigations must be instituted before the fundamental causes of softening, loss of color, hollow pickles, etc., will be clearly understood. The question of the value of pure cultures has not been sufficiently studied to justify the extensive conclusions at which some investigators have arrived.

One of the troubles in cucumber fermentation is formation of a scum over the surface of the pickle brine. In this are many pseudo-yeasts which eat the acid and thus lower the preservative value of the pickle brine. Rahn⁸² suggested that ultraviolet light might be used to control this scum. Daily radiation for 30 minutes kept the surface of brine free from *Mycoderma*. Growth of these *Mycoderma* is influenced by salt content of the brine.

Authentic cultures of *Debaryomyces* and *Mycoderma* obtained from ordinary culture collections by Mrak and Boner⁸³ had a much lower salt tolerance than those obtained from pickle brines. Strains of *Debaryomyces* isolated from food brine could resist a salt concentration of 24 per cent and those of *Mycoderma*, 15 per cent. Other factors than film yeasts may also disturb the acid balance of brine tanks in pickle curing. Fabian, Bryan, and Etchells⁷⁵ stated that lime or sodium bicarbonate, by neutralizing the acidity produced by the acid-forming bacteria, creates a condition favorable for proteolytic bacteria, but should never be added to fermenting cucumbers and should be reduced to a minimum by every possible means. Very hard water is also undesirable, and only high-quality salt should be used. Acetic acid, to control cucumber fermentation, was found unnecessary, but a small amount was apparently beneficial in 30° salometer brine. Acetic acid added to high-test brines, such as 40° salometer, seemed detrimental since it apparently delayed fermentation. "A high acetic acid content in the presence of a high salt concentration is an undesirable combination."

83. Mrak and Bonar. 1939. *Zentbl. Bakt.*, Pt. 2, 100, 289-294.

Environmental conditions influence markedly the course of the cucumber fermentation. Among them temperature plays an important role. Fabian, Bryan, and Etchells⁷⁵ found the acidity of a barrel of cucumbers kept outdoors to be nearly twice as high as that of a barrel kept indoors, the acidity disappearing much more rapidly from the barrel kept indoors. Barrels outdoors had a more gradual fermentation with a higher acid production, and the acid persisted much longer. It was found necessary to be more careful about the salt concentration in the case of outdoor tanks than it is with indoor tanks. The top layer of cucumbers from an unweighted barrel showed signs of spoiling within 24 hours as evidenced by soft spots on the surface—a possible explanation of layers or areas of soft pickles in a vat of pickles otherwise prime.

In view of the fact that organic acids formed from sugar by microorganisms are the important preserving agents in pickle brine, some investigators have suggested that larger amounts of these acids might be formed if sugar were added to the brine. Fabian and Wickerham⁸⁴ found that addition of two pounds of sugar per barrel increased the number of bacteria at the beginning of the fermentation. This was considered to be desirable because it would result in prompt acid formation.

Contrary to results of others, Veldhuis, Etchells, Jones, and Veerhoff⁸⁵ found that addition of sugar to fermenting cucumbers caused no significant change in brine acidity. Apparently no increase in fermentative activity of microorganisms was caused. On the other hand, they reported a large increase in proportion of bloaters during production of either salt stock or dills.

The gases evolved from pickle fermentations have been shown by Veldhuis and Etchells⁸⁶ to be mainly carbon dioxide and hydrogen. A study was made of the gases evolved during vat fermentations in salt brines of 20, 30, 40, 60, and 80 per cent saturations, with subsequent increases in brine concentration to 70 per cent saturation in six weeks. Carbon dioxide was found in the gases from all fermentations. Hydrogen was produced in considerable amounts from all fermentations in 60 per cent saturated brines and in smaller amounts of some fermentations in 20, 30, and 40 per cent saturation. Hydrogen was also produced in 80 per cent brines, but the gas evolution was slow. Organisms capable of producing hydrogen were isolated from brines.

Pure Cultures in Pickle Fermentation. The evidence on the value of pure-culture inoculation on pickle fermentation is not clear cut. Kossowicz⁸⁷ reported that bacteria isolated from pearl onions and garlic markedly facilitated acidification of pickles and prevented softening. LeFevre⁸⁸ found pure cultures to yield good results because they favored the initiation of an active fermentation. He believed that the organism *Lactobacillus brassicae* was the cause of pickle fermentation. LeFevre could observe no

benefit from acidulating fermenting cucumbers with lactic acid. The use of pure cultures in pickle fermentation should be considered from two viewpoints, whether they are necessary or whether they improve the product. They may not be necessary but it would probably be wrong to deny that they might improve the quality.

If pure cultures are not used, the pickle maker may attempt inoculation of a large tank by dumping a barrel of fermenting cucumbers into it. One must be certain, however, that the starter is a good one, else a weak fermentation may result.

DETERIORATION OF BRINE PICKLES

Some manufacturers have suffered serious losses owing to microbial activities and improper handling. Most of them may be attributed to abnormal fermentations.

Slippery, Soft, and Mushy Pickles. While many different reasons have been given for appearance of this type of spoilage, microorganisms and abnormal fermentation are the most reasonable explanation. Some manufacturers find layers of soft pickles in tanks. The tank may be so large that it is not filled quickly. Some of the cucumbers may not be forced under the brine until the tank has been filled. Fresh cucumbers float in the brine. In this manner, spoilage bacteria may grow and soften the cucumbers before the preservation agencies owing to fermentation can function. Softening is probably stopped as soon as an active fermentation is started. Softening may also develop after curing. This is a slow process. When it appears the pickles are usually worked up into some of the special types, such as sour, spiced pickles, etc.

Softening may be due to decomposition of acid by film yeasts. Joslyn⁸⁹ classed such yeasts with *Mycodermae*. Wehmer⁵¹ described two species under *Mycoderma* I and *Mycoderma* II. Janke⁹⁰ attempted to find some method of preventing the development of these organisms. They were found to be sensitive to acetic acid; at 30°C. (86°F.) .6 per cent inhibited them. Allyl mustard oil was suggested for controlling these organisms in pickle tanks. While it prevented development of *Mycoderma*, it is not used to any extent. One of the earliest reports on the subject was published by Aderhold,⁷⁸ who believed that spoilage was due to the activities of *Escherichia coli*. Kossowicz⁸⁷ disagreed, and quite conclusively from Aderhold's paper, that this organism was not the cause of spoilage. Aderhold reported that his plates showed large numbers of liquefying bacteria. Kossowicz believed that Aderhold was wrong in not considering these liquefiers. Several years later, in his contribution to Lafar's *Handbuch der technischen Mykologie*, Aderhold still held to his original idea that *Escherichia coli* caused soft pickles. Kossowicz's investigations were made at the request of a pickle packer who had had frequent trouble with softening of fermented pickles. He proved experimentally that *Escherichia coli* did not spoil pickles and that several aerobic- spore-forming bacteria

89. Joslyn. 1927. Fruit Prod. J. and Amer. Vinegar Indus. 6, 22-23.

90. Janke. 1923. Amer. Vinegar Indus., March, 1923, 17-18.

did. Further work was published in 1909. LeFevre⁹¹ isolated 50 organisms, 16 of which caused softening to a greater or lesser degree. *Bacillus vulgatus* showed the highest salt and acid tolerance. LeFevre believed that a wide range of bacteria could decompose cucumbers. In several publications, he stressed the necessity of keeping unfit stock out of brine tanks. Kossowicz⁹² and Aderhold⁷⁸ recommended prompt fermentation if defective pickles were to be avoided. Kornauth and Zanoluchi⁹³ believed that *Bacterium g  ntheri* was the organism to be favored and that this species was identical with some of the bacteria reported by others. This type of spoilage, according to Fabian, Bryan, and Etchells,⁷⁵ is accompanied by marked morphological evidence of decomposition of tissue. An organism from spoiled pickles isolated by Fabian and Johnson⁹⁴ corresponded to *Bacillus mesentericus fuscus*; it was capable of causing "slips" in six to 12 hours and "mushy" pickles within 12 to 24 hours. This organism grew well in concentrations of salt up to and including nine per cent and more slowly up to 11 per cent.

Floaters. Pickles which, owing to some cause, float on the surface of the tank are known as "floaters." They may be caused by hollow spaces in the pickle or even to gas formation by bacteria which gain entrance through abrasions. LeFevre,⁹¹ who carried out extensive investigations for the Bureau of Chemistry, found that most floaters were hollow. He also stated that improper salting might cause floaters. Floaters may be prevented by using stock which does not run to hollow cucumbers and the prevention of infection of the cucumber by careless handling. There seems to be no real explanation for floaters. The varying density of the brine in the pickle tank might explain it. Another opinion offered to explain floaters has it that the skin of the cucumber may be made tough and intact so as to prevent the exit of gases which, when retained, buoy up the cucumber. That salting modifications may greatly influence formation of floaters was also indicated by Jones, Etchells, Veerhoff, and Veldhuis.⁹⁵ Relatively large numbers of floaters were secured when brines of high salinity were used during the early portion of the curing period in salt stock production. Floater formation was said to be related to gaseous fermentation. This was probably confirmed by Etchells and Jones⁹⁶ who observed, by microscope examination, presence of many dead yeast cells in brine from a batch of pickles among which were many bloaters.

Black Pickles. Old brine pickles are apt to turn black if the acidity is low. The blackening is accompanied by a strong odor of hydrogen sulfide; the black color is probably nothing but iron sulfide formed from the iron in the water with the hydrogen sulfide. The hydrogen sulfide is in all probability formed from the gypsum in the water. Most waters contain a little gypsum and iron. Bacteria liberating hydrogen

91. LeFevre. 1921. *The Canner* 52, 207.

96. Etchells and Jones. 1941, *Idem* 20, 370.

sulfide from gypsum are found commonly in soils and in mud at the bottom of rivers and lakes. Especially *Spirillum* forms are noted for that. Tanner⁹⁷ has shown that many common bacteria and yeasts are able to reduce sulfur compounds with the formation of hydrogen sulfide. Fabian and his colleagues also found that small quantities of iron compounds together with the formation of hydrogen sulfide in the brine caused black pickles. It occurred only in nearly neutral or alkaline brines, began at the top of the brine, was accompanied by an odor of hydrogen sulfide with or without the odor of other putrefactive products, and was retarded, though not prevented, by a one-inch layer of mineral oil on the surface of the brine. Softening appeared not to be related to brine blackening except in that both required a neutral or alkaline brine for development. Combined softening and blackening were accompanied by a strong ammoniacal odor. Addition of a sugar, dextrose or sucrose, to the brine after the active fermentation has ceased seemed to be beneficial when pickles were stored for any length of time. There is a sufficient number of acid-producing bacteria left to cause a considerable increase in the acidity.

Bacillus nigrificans was isolated by Fabian and Nienhuis⁹⁸ as an organism causing black pickles. It is a spore-forming rod which produces blackening by a water-soluble pigment. Conditions favoring blackening are presence of a carbohydrate, absence of an excessive amount of nitrogenous material, and a neutral or slightly alkaline brine.

Ropy Brine. Capsulated bacteria cause trouble in several foods preserved by methods which require activities of certain bacteria. Thirteen cultures of bacteria, isolated by Fabian and Nienhuis from four samples of ropy brine from Michigan and Wisconsin, were divided into two groups on the basis of morphological, cultural, and physiological characteristics. Group I (seven cultures) consisted of bacteria which were short and generally motile, gram-negative, encapsulated rods not fermenting any of the carbohydrates tested. Group II (six cultures) consisted of bacteria which were motile, gram-negative rods, somewhat longer than those of Group I: three members of this group were encapsulated. The 13 cultures produced the greatest amount of ropiness in a brine of low acidity and salinity: rise in temperature also favored ropiness. The rough forms of the two groups studied produced little or no ropiness, as compared with the smooth forms. Ropiness is most easily controlled by increasing the salt concentration about twice as fast as normal.

Hollow Pickles. Hollow pickles are the cause of considerable loss in some factories, while others do not seem to have this trouble at all. The reasons given by manufacturers are very different. Season, temperature, too fast fermentation, too strong brine, too weak brine, imperfect growth are possible explanations. It seems to be true that the cucumbers of the late season show more tendency to become hollow than the first crop. This tends to show that the trouble lies in the structure of the cucumber perhaps rather than in the method of fermentation. LeFevre⁷⁴ stated that

97. Tanner. 1918. J. Amer. Chem. Soc. 40, 663-669.

98. Fabian and Nienhuis. 1934. Mich. Agr. Expt. Sta. Tech. Bull. 140.

hollow pickles were due to too long an interval between harvesting and curing.

After the pickles are removed from the brine tanks, they are made into different varieties, such as dill, sour, spiced, etc. Some are canned and given a process to destroy bacteria and prevent respiratory changes.

Pasteurization of Pickles. In order to reduce and eliminate deteriorative changes in stored pickles, they have been pasteurized in order to destroy microorganisms. Jones, Etchells, Veldhuis, and Veerhop⁹⁹ observed persistence of many microorganisms in pickles stored for a considerable time and a low number of bacteria in pasteurized pickles. In unpasteurized pickles acid-forming bacteria and yeasts predominated while these species were destroyed by pasteurization. The bacteria found in the latter were resistant sporeformers. The same results were reported by Etchells and Ohmer,¹⁰⁰ who pasteurized pickles at 71.1°C. (160°F.) for 20 minutes or 73.9°C. (165°F.) for 15 minutes. Little or no increase was noted during storage. Similar conclusions were reached by Etchells and Goresline.¹⁰¹ Jars of pickles pasteurized at 71.1°C. for 20 minutes retained their fresh appearance and most of their crispness during several months' storage. Pasteurization temperature of 71.1°C. was sufficient in Etchells' and Jones'^{101a} experiments to destroy both acid-forming bacteria and yeasts irrespective of the inoculum used. Acidity was an important factor in destruction of microorganisms by pasteurization.

Preservation of Vegetables by Salting. Owing to scarcity of tin and rubber at the time this is written, attempts are being made with considerable success, to preserve various vegetables by salting. Brine concentrations of 40°, 60°, and 80° salometer have been used. The microbiological changes are apparently quite similar to those observed in making cucumber pickles.^{101b, c}

OLIVES

Olives have been used by man since earliest times. Besides the olive itself, its oil has been pressed for human food. The industry was developed in Greece and Spain and was later introduced into California.

The method of pickling olives as it is practiced in Greece and Spain today has much in common with the methods used in California. These have been described by Kaloyereas¹⁰² and Trabut.¹⁰³ Cruess,¹⁰⁴ who reviewed the history, technology, and preservation of olives, credited the old Mission Fathers with introduction of various fruits, some of which are known today as "Mission" varieties. Olives are picked when firm and ripe and are shipped to the factory in light brine in barrels. Cruess stated that they are handled much like cucumbers, the same type of lactic ferment-

tation being induced, during which time the fruit becomes firmer and the sugars change to lactic acid. This author stated that the terms "curing" or "processing" are now used in preference to the older term "pickling." The changes which occur during the curing process have been discussed by Lesley, Cruess, and Kaloyereas.¹⁰⁵ These will not be reviewed in this book because they were mainly chemical in nature. Cruess¹⁰⁶ stated that the olives are put into 50-gallon barrels and salted with from five to 10 pounds of salt. The olives are fermented in about the same manner as are brine pickles. Differences of opinion apparently obtain with regard to the value of pickling. Cruess believed that if it is necessary to hold olives, they should be placed in a strong brine which will prevent all fermentation. He advised starting the olives in a five-per cent brine and increasing the concentration to 10 per cent. Such treatment will prevent shriveling and sliminess and keep the olives free from molds. Ripe olives are often put into a lye solution to remove a bitter principle. After removal of the lye by soaking, the olives are put in dilute brine, after which they are sorted and canned. A temperature of 115.6°C.(240°F.) for 60 minutes is used for processing both in glass and in tin. In California, this step in olive canning is under the supervision of the State Board of Health. After processing, the cans and jars are cooled in water.

More extensive investigations of the ripening of olives were reported by Cruess.¹⁰⁷ As far as the use of high temperatures is related to the merchantable qualities of olives, Cruess found that there was no difference. It seemed that olives which were sterilized at 115.6°C.(240°F.) and 121.7°C. (250°F.) possessed as good taste and flavor to the average consumer as those sterilized at 100°C.(212°F.) for 40 minutes.

The floral changes occurring in fermentation of Manzanillo olives was found by Vaughn and Douglas¹⁰⁸ to be quite similar to those in the fermentation of sauerkraut, with the important exception that gas-forming species of *Lactobacillus* apparently play no role in olive fermentation. During the early stages of olive fermentation coliform and other gram-negative bacteria predominate. They are soon crowded out by *Leuconostoc* types. These in turn are replaced by *Lactobacillus plantarum* which carry the fermentation to completion. Vaughn and Douglas observed both film-forming and non-film-forming species of yeasts which were believed to have a role in flavor and aroma formation.

Olives are subject to several deteriorations as are other fermented foods. Bioletti¹⁰⁹ stated that overripe olives often became soft during fermentation, especially in lye solutions. Salt is used in the lye to prevent it. Kosowicz¹¹⁰ believed *Escherichia coli* to be the cause of softening of green olives stored in brine. A lactic acid fermentation stopped the spoilage. On the other hand, West, Gilliland, and Vaughn¹¹¹ did not find this organ-

ism to be important in olive spoilage. In fact no true *Escherichia coli* were found. *Aerobacter* made up about 70 per cent of the cultures examined while the rest were intermediates. Tracy¹¹² also failed to report *Escherichia coli* among several coliform species isolated from spoiled olives. The species isolated were *Escherichia neopolitana*, *Escherichia pseudocoloides*, *Escherichia iliaca*, *Aerobacter cloacae*, and occasionally several other members of the genus. Fermentation tanks were believed to be contaminated by dust and water supplies.

As is the case with pickles, olives are subject to another type of spoilage yielding what are known as "floaters." Alvarez¹¹³ found three types of bacteria involved. During fermentation the olives became covered with blisters which caused them to rise to the surface. Even though no spores were formed the bacteria which were believed to cause floaters were resistant to salt, heat, acids, and alkali. To prevent this deterioration frequent cleaning of the vats was recommended.

Tracy¹¹⁴ believed that good results followed the use of starters in factory tests on olive curing. The bacteria used were originally isolated from holding solutions although Tracy suggested that sediment from holding solutions might be used if they were carefully handled. Large numbers of cells are necessary, about one-half billion per milliliter of brine, before fermentation is initiated. It was suggested that, if olive sugar could be fermented to acid before coliform bacteria could ferment it, no spoilage would occur in the holding brines. Furthermore, flavor would probably be improved.

Pasteurization procedures have been introduced for ripe olives in process in order to prevent attack by bacteria which may develop between lye treatments. The temperature and time is determined by the amount of time which the olives will stand. Too much heat will result in olives with a soapy taste because of reaction of the lye with the oil in the olive. Cruess¹¹⁵ stressed the necessity of experiments to determine the time and temperature which could be used.

Canning of Olives. After being cured, sorted, and graded the olives may be packed in either metal or glass containers. The cans are exhausted for a few minutes near the boiling temperature until the center of the can reaches a temperature of 85°C.(185°F.). They are then closed and processed.

Processing of canned olives in California is done according to regulations of the Cannery Inspection Division of the California State Department of Public Health. Each retort is provided with temperature recording devices and a record kept for every batch cooked. The process times and temperatures are based on results of investigations conducted by the University of California. Glass containers are closed under vacuum and are processed in water at 115.6°C.(240°F.) for 60 minutes. Since introduction of this process, spoilage has been eliminated and botulism prevented.

Warth ¹¹⁶ summarized spoilage of brine-packed olives as follows:

- a. Molds owing to faulty fruits.
- b. Bacteria, mostly of the lactic acid type, manifesting themselves as colonies in the form of tiny white spots on packed fruit.
- c. Sediment and cloudiness. This may be caused by deterioration of the product or packing under undesirable closure.
- d. Yeasts owing to contamination.
- e. Staining of cap liners. The liner of a cap will undergo decolorization through careless methods of packing or imperfect sealing.

Clouding of Olive Brine in Glass Jars. Clouding of olive brine accompanied by white flaky deposits is not an uncommon occurrence in bottled olives. Clouding of green olive brine may be due to calcium and magnesium salts in the water used in making the brine or to presence of microorganisms. Among the latter are the so-called film yeasts and bacteria which are able to withstand the conditions in the olive brine. If curing of the olives is carried to completion before any attempt is made to pack them in glass or tin containers, little, if any, trouble will be experienced with clouding. If, on the other hand, curing is not complete, it will continue in the fresh brine in the containers and of course, be accompanied by clouding. Various means have been attempted to prevent such trouble. Reduction of the oxygen content by filling the jar completely and vacuum sealing is one remedy. Pasteurization ¹¹⁷ is another, for it has been found that short heating at 54.4°C.(130°F.) will easily destroy the yeast.

Ayers, Barnby, and Voigt ¹¹⁸ considered the function of *Mycoderma* in this type of spoilage. Bottles of olives frequently show the presence of film on the surface. In order to prevent the appearance of this film, Ayers and his colleagues studied the effect of concentration of salt, exclusion of oxygen, and application of heat. It was found that salt concentration could not be relied upon to control development of the yeast and still have a merchantable product. The data secured by Ayers were in accord with those secured by Cruess,¹¹⁹ showing that growth of *Mycoderma* was not prevented by eight per cent of salt and that at least 18 per cent was necessary to stop its growth. Exclusion of air was found to prevent development of the yeast. It was found that vacuum packing of the olives restricted the fungus. The next step was to determine whether heat could be used to destroy the organism. In a four-per cent brine, the organism was not destroyed by heating at 130°F., for five minutes. However, in this concentration or brine it was destroyed in five minutes. It is very interesting to note, however, that when the salt concentration was 14 per cent, the temperature required to destroy the yeast was slightly lowered. The authors believed that heating of the bottles of olives after packing might be of value in practice.

Ripe Olives. After being picked the olives are put into wooden barrels or tanks in brine of at least 25° salometer. After several weeks, the olives are subjected to a lye treatment to destroy the natural bitterness. Following this treatment they are thoroughly washed in water to leach out the lye. They are then packed in brine with two to three per cent of salt. After standing for a few days, they are ready for packing in glass or tin containers. Some are sold in bulk. Under regulations of the California State Department of Public Health¹²⁰ all bulk ripe olives must be held in kegs or barrels in a brine solution containing at least two and one-half per cent of salt (10 per cent brine).

TEA

Tea is prepared by fermentation processes which are probably not microbiological to any extent. More important are enzymes in the leaf. Green tea is prepared by roasting the leaves soon after picking to prevent fermentation, while black tea is allowed to stand during which time a slow drying process occurs. Mann¹²¹ and Newton¹²² believed the important enzyme in the tea leaf to be an oxidase and that the leaf should be handled so as not to harm it. Most investigators, among whom are Tunsdall,¹²³ Straub and Deuss,¹²⁴ Bernard,¹²⁵ Evans,¹²⁶ and Tatarskaya,¹²⁷ are agreed that microorganisms are not involved in normal tea curing. Straub and Deuss tried to use pure cultures of yeasts but observed no improvement in flavor. Bernard, however, isolated a yeast from Java tea which seemed to improve the flavor. Since it is possible to produce fermentation in completely sterilized leaf, Evans reasoned that microorganisms are not essential. On the other hand, rapid development of microorganisms took place at temperatures higher than those which allow fermentation of the leaf. Yeasts were harmless but any development of bacteria or molds resulted in dark or yellow liquors with characteristics of over-fermented tea. Tatarskaya also believed microorganisms to have no function in tea fermentation. They are always present on leaves, as shown by Itano and Yasuhiko,¹²⁸ who followed their development under different conditions. Bacteria and fungi were observed to survive the entire process although their number decreased toward the end.

Molds were observed by Nakazawa *et al.*¹²⁹ to spoil tea leaves destined for black tea. Members of the genera *Aspergillus*, *Penicillium*, and *Rhizopus* were isolated. When they grew on tea leaves the extractive was soon rendered unpalatable. Dry heat used in preparation of the leaves and strict cleanliness aided in controlling these fungi.

Germicidal Action of Tea Infusion. *Eberthella typhosa*, according to Dold,¹³⁰ was not destroyed in 80 days in .25 per cent infusion of black tea or in .50 per cent cocoa solutions. In four per cent green tea, it lived for 20 days. These data indicate that pure water must be used for these beverages. Ropiness in tea reported by Greene, Judd, and Marx¹³¹ confirms this statement. Ropiness was found to be due to *Aerobacter aerogenes* which came from the water supply.

COCOA AND CHOCOLATE

These products are prepared by grinding the seed of the cacao plant. The seeds are enclosed in a woody shell which is removed by a special fermentation. The beans are piled into boxes where they undergo a spontaneous fermentation which loosens the shell. Bainbridge and Davis¹³² described the process as it is carried out in the West Indies and South America. The beans in the fermenting box become warmer as fermentation continues. After five or six days the temperature may reach 45 to 50°C. (113 to 122°F.). The first stage is accompanied by a vigorous growth of *Saccharomyces apiculatus* and *Saccharomyces anomalus*. The second stage is an alcoholic fermentation by true *Saccharomyces*. Development of *Acetobacter* is the third stage. Later aerobic, sporeforming bacteria may develop. This fermentation results in an improved flavor. Fermentation thus serves two purposes. (Wigman.¹³³) *Saccharomyces theobromae* was isolated by Preyer¹³⁴ and Lambert.¹³⁵ Loew¹³⁶ also believed that yeasts were important. They were believed to develop in the juices which came from the pulped tissue.

After discussion of literature and review of methods used in different parts of the world, with studies on predominating yeast flora at different stages of fermentation, Lilienfeld-Toal¹³⁷ emphasized the value of pure-culture control, and found that in all parts of the world the same yeasts are concerned. The two species invariably present are *Saccharomyces ellipsoideus* var. *tropicus* and *Schizosaccharomyces bussei*. Other yeasts are present, but play no role. Steinmann¹³⁸ isolated four kinds of yeast from the sweating boxes on several estates in central Java: *Mycoderma*, which grew when the temperature was kept below 30°C. (86°F.); a true wine yeast of *Saccharomyces ellipsoideus* group, occurring later when the temperature of the beans has become between 25 and 40°C. (77 and 104°F.); an ascospore forming variety; and finally an *Apiculatus* type. On some estates, the temperature during the first 24 hours is below 30°C. (86°F.) since the fermentation is carried on in houses which are not protected from cool air at night. On estates where closed houses are used, the temperature is higher. A rather heterogeneous flora of microorganisms was

reported by Busse, Henneberg, and Zeller.¹³⁹ The fermentation process was said to start with yeasts and bacteria. During fermentation, increase in temperature makes the conditions favorable for acid-tolerant, thermophilic, sporeforming bacteria. Attempts to use pure cultures of organisms for hastening fermentation were not successful. *Thermobacterium mobile* was suggested for supplementary fermentation before manufacture by Borghi *et al.*¹⁴⁰

Spoilage of cacao beans, especially when moist, may be induced by molds. Several groups of molds were described by Bunting,¹⁴¹ all of which came from cacao beans. Most of them were ordinary species which are present in air and dust. Five species of *Actinomyces* were isolated by Ciferri from cacao beans which gave off a moldy or earthy odor. They were found either on the rind of the fruit or in the fermentation receptacles whence they contaminate the beans. Acid from the fermentation inhibits but does not kill them. Ciferri believed that proper handling would control these fungi.

Inhibition of Microorganisms by Chocolate. Some evidence has been published to indicate that chocolate may be inhibitive if not germicidal for microorganisms. Tanner and Snyder¹⁴³ observed shorter survival times of bacteria in chocolate fudge than in plain fondant. Cathcart and Merz¹⁴⁴ reported growth of *Staphylococcus aureus* to be effectively inhibited by fillings made with natural chocolate and natural cocoa. The inhibitive substance was believed to exist in the non-fat portion of the cocoa.

COFFEE

The beverage coffee is an extract of berries from the coffee tree *Coffea arabica*. The coffee berries grow in clusters or rosettes, each berry containing a soft pulp surrounded by a membrane. Inside the pulp are two coffee beans surrounded by a parchment membrane. In order to prepare the coffee beans for commerce, the extraneous pulp must be removed. This is done in one of two ways, by a *dry method* or *wet method*. In the former method the berries are spread in thin layers for exposure to sun and air for three weeks. This thoroughly dries them so that the extraneous material may be removed by hulling machines. In the latter, the wet method, the berries are softened by soaking in large tanks in water for 24 hours. The berries are then passed through pulping machines which remove the outer covering and pulp. This leaves the two berries within the parchment covering. The beans are then allowed to ferment in large tanks which further softens the membrane about the berries. They are then dried and finally "hulled" or shelled.

Fermentation of coffee has a primary purpose in removing the slimy "saccharine matter" from the parchment. Beckley¹⁴⁵ found that the active

agent in the cleaning was an enzyme in the "saccharine matter" and that microorganisms are not strictly essential to the process. However, use of certain bacteria was found of value in hastening cleaning, through fermentation of fermentable sugars formed by decomposition of the "saccharine matter." In addition, a favorable level of acidity was maintained. Beckley believed that, providing proper precautions are taken, inoculation with favorable bacteria will save time in fermentation and will improve the quality of the coffee.

Germicidal Properties of Coffee Infusion. A few investigators have suggested that coffee infusions possess germicidal properties. Crane and Friedlander¹⁴⁶ stated that ground coffee, when mixed with yolks and whites of eggs and with chopped beef, prevented decomposition. Coffee infusion exposed to air became covered with mold growth but never turbid with bacteria. A 10-per cent infusion prevented development of *Eberthella typhosa*, *Escherichia coli*, and *Bacillus anthracis*. They did not ascertain to what constituent of coffee the germicidal action should be attributed. Dold,¹⁴⁷ using six per cent infusions of coffee, observed *Eberthella typhosa* to be killed in one to three days, the resistance varying with the strain. Aging of the infusion caused it to lose some of its germicidal properties. *Salmonella schottmülleri* was a little more resistant, surviving for 14 to 15 days.

Soy and Related Fermentations. Soybean sauce is a dark brown-black fluid prepared in the Eastern countries by the fermentation of soybeans. The subject was well reviewed by Church.¹⁴⁸ The manufacture of the soybean sauce, called "shoyu" in Japan, involves first of all a preliminary mold fermentation followed by ripening in brine. After the soybeans have been cooked and mixed with prepared wheat they are inoculated with a mold-starter called "tane-koji." This is a rice preparation heavily overgrown with the mold. The species of mold varies somewhat. Miss Church stated that the species was *Aspergillus flavus* Link; occasionally *Aspergillus oryzae* or species between these two are used. This preliminary mold fermentation is carried out in shallow wooden trays which in Japan are stored in rooms, in cold weather they may be heated. The soybeans are first soaked for about 20 hours with frequent changes of water in order to prevent souring. A rapid fermentation occurs from the growth and activities of a sporeforming, rod-shaped organism. To prevent this, the water is changed frequently. After soaking, they are cooked until soft enough to be pressed flat between the thumb and finger. After cooking, the beans are spread out to cool. Wheat is crushed unevenly and roasted to a dark brown color. The boiled beans and roasted wheat are then mixed thoroughly so that the beans are separated from one another by the wheat. The mixture is then inoculated with mature rice koji, a pure culture of the mold, or some previously molded material. The inoculated mass is then placed in koji tray and placed in the koji room maintained at about 25°C. (77°F.). The mix

146. Crane and Friedlander. 1903. Amer. Med. 6, 403-407.

148. Church. 1923. U. S. Dept. Agr. Bull. 1152.

ture is stirred at intervals and is matured between 24 and 48 hours. When the mixture has sufficient growth of mold, it is emptied into a tube of brine of a strength of 20-22° Baumé. Each tube is inoculated on the first day with *Zygosaccharomyces* sp. The budding fungi of "shoyu-moromi" were studied by Takahashi and Sano.¹⁴⁹ They found two varieties of film-forming *Zygosaccharomyces* which were varieties of *Zygosaccharomyces salsa*. Since they differed from this species by fermenting saccharose, raffinose, and alpha-methylglucoside, Takahashi and Sano suggested the name *Zygosaccharomyces salsa* var. *saccharosum* I and II.

Under American conditions Church secured a satisfactory product. Similar sauces were also made from peanut press cake.

Sixteen aerobic bacteria and 12 anaerobes, isolated by Tshimaru¹⁵⁰ from soy mash, were found to grow in 10-per cent salt solution. Half of them grew in a 20-per cent solution. In manufacture of soy, the bacteria accelerated hydrolysis of protein and polysaccharides by the mold (*Aspergillus*). Several bacteria were named which were especially useful in soy manufacture. Most of them are well-known diastatic species.

Some evidence has been published to show that soy sauce may be inimical to bacteria. Worcestershire sauce, an important constituent of which is soy sauce, was reported by Tetsumoto¹⁵¹ to have a strong sterilizing action.

POI

This, according to Allen and Allen,¹⁵² was one of the chief foods of the old Hawaiians, and is used today in the Hawaiian Islands. It is made by pounding the steamed roots of the taro plant *Colocasia antiquorum* var. *esculenta* into a smooth paste with addition of small quantities of water. While it may be eaten immediately, it is most desired after it has fermented several days. Allen and Allen reported the flora of various samples of poi with an acidity not greater than pH 4 to consist largely of bacteria and yeasts. The bacteria were mainly coliform types. Poi that was older than three days or with acidity greater than pH 4 showed few coliform bacteria but many bacteria growing as pin-point colonies. Bilger and Young¹⁵³ believed that the fermentations involved in poi manufacture were carbohydrate decompositions with various fatty acids resulting.

CITRON

This is prepared in Corsica by fermentation for use in confections. Hollande and Chadeaux¹⁵⁴ described a yeast as important in the fermentation to which he gave the name *Saccharomyces citri medicae*; a bacterium, *Bacillus citri medicae* was also an important fermenting agent. Citron prepared in Corsica by this method had a superior aroma caused by esterification by yeast of the essence of citron. Hollande and Chadeaux¹⁵⁴

suggested that the citron could be sterilized by steam and a pure-culture fermentation instituted. In the United States this fermentation has been studied by Fellers and Smith,¹⁵⁵ who confirmed the work of Hollande and Chadeaux as far as fermenting organisms are concerned. Acetic acid production in 15 days averaged from six to seven grams per liter. Preserving citron 35 per cent of glucose with sucrose yielded a peel with excellent flavor, color, and texture. A moisture content of 17 to 19 per cent in the candied peel prevented yeast fermentation or mold growth.

CHAPTER 19

MICROBIOLOGY OF SUGAR AND SUGAR PRODUCTS

Sugar is so necessary in present day cookery and nutrition that its place and importance is recognized only when some event arises to reduce its availability. On account of the nature of the substance and the methods necessary to purify it, sugar is especially subject to the attacks of yeasts, molds, and bacteria. These microorganisms cause much spoilage and the spending of much money to check their activities. The character of the raw materials, beets, cane juice, and maple sap, from which sugar is made, explains the sources of many bacteria. They are usually heavily seeded with microorganisms from the air, water, soil, etc. These start through the process of sugar manufacture in the juice, and many of them which are sporeformers are able to persist for some time.

Of all the sugars, cane sugar, prepared from the succulent stems of the sugar cane (*Saccharum officinarum*), is probably the most satisfactory, although beet sugar is becoming an important article. The preparation of cane sugar for the market is a process too long for detailed discussion in a book of this nature. However, the main step is extraction of juice from the cane, which is usually accomplished by crushing and squeezing the cane stalks between rollers. Under the most ideal conditions from seven to 10 per cent of the weight of cane will be secured as sugar. Extraction of the juice by diffusion is not followed so much with cane as with beets. After crushing, the next step is purification of the juice. When it comes from the rolls, it contains all of the materials which were in the juice when it was pressed out of the cane cells. The juice begins to change just as soon as it is out of the cells of the plant and this should be stopped. Lime is added to neutralize the acids and stop inversion. The mixture is then allowed to settle. The juice which flows from the separators is concentrated to a thick sirup previous to the final concentration and crystallization. Great advances have been made in this step by vacuum pans and other devices for driving the concentration process more rapidly. The vacuum pan is used in the crystallization which leaves the sugar as crystals suspended in a noncrystalline sirup or molasses.

Gum Formation in Sugar Manufacture. This is a very troublesome deterioration which causes considerable loss to sugar manufacturers. The same slimy fermentation so often met with in other sugar-containing substances is encountered in making sugar. Many organisms have been described. The usual rod-forming, sporebearing bacteria have been found. Glaser¹ described *Bacterium gelatinosum betae*, while other organisms have been mentioned by Maassen,² Schöne,³ and others.

1. Glaser. 1895. Centbl. Bakt., Pt. 2, 1, 879-880.

2. Maassen. 1905. Idem, 15, 66; 16, 236.

3. Schöne. 1904. Ztschr. Ver. Rubenzuckerindus. 54, 1060.

The air of sugar mills was shown to be seeded with the microorganisms which cause decomposition of the sugar, by van der Bijl⁴ who reported the presence of the following: *Aspergillus flavus*, *A. parasiticus*, *Monilia* sp., *Cladosporium* sp., *Penicillium divaricatum*. Gum formation was early recognized by Greig-Smith.⁵ He called the gum levan. Kopeloff, Perkins, and Welcome⁶ identified levan formed by the enzymes produced by *Aspergillus sydowi*. In order to study the mechanism of levan formation, these investigators set up sucrose solutions of varied concentrations and analyzed them for sugars and gum. The latter was thought to be formed from dextrose and levulose by levanase from mold spores. These sugars are formed from sucrose by invertase. In the absence of nascent glucose little gum was formed.

Violle⁷ reported that the organism responsible for formation of gum in sugar was much like *Streptococcus lacticus*. Large capsules were formed which caused the bacteria to adhere in very large masses. Capsule formation, however, seemed to depend upon the medium on which the organism was propagated. A viscous material was formed in the sugar; saccharose seemed to be the only sugar in which this material was formed. This material was precipitated by alcohol. The experiment of Owen⁸ indicated that gum formation was favored by a slightly alkaline environment. He also found that at least one per cent of moisture had to be present. Pederson⁹ believed that this spoilage could be prevented by greater cleanliness and more rapid handling of the cane and juice previous to and during heating. He isolated many species (over 300) among which was *Leuconostoc mesenterioides*. It occurred in many of the samples.

MICROBIOLOGY OF RAW SUGAR

Much work has been done on the microorganisms in raw sugar. Owen⁸ summarized most of the earlier literature. Gayon¹⁰ observed that changes which took place in stored sugar were fermentations favored by moisture and high temperature. In 1878 he reported that they were accompanied by decrease in sucrose content and increase in dextrose and levulose content. Many microorganisms were found in these samples, activities of which could be checked with certain chemical compounds. The subject has been reviewed also by Church.¹¹ Owen¹² classified the organisms occurring in sugar into three groups—mold fungi, yeasts, and bacteria. They are named in the order of their importance in connection with sugar deterioration.

Molds. The species that have been found are quite varied and represent almost all of the well-known genera. Payen¹³ observed presence of fungi

and connected them with spoilage. Contributions to the subject were made by Kamerling,¹⁴ Shorey,¹⁵ Greig-Smith,¹⁶ Schöne,¹⁷ Scott,¹⁸ Amons,¹⁹ and others. According to Owen,²⁰ possibility of molds causing spoilage in sugar was first mentioned by Shorey.¹⁵ Owen, however, gave more information on this question. Different species of molds were isolated as follows: *Aspergillus niger*, *Asp. fumigatus*, and quite a number of *Aspergillus*-like fungi. These were carefully tested for their action on sugar solutions. In almost every case strong deteriorating action of the fungi was noticed in the sugar solutions in which these fungi were inoculated. These molds possessed a strong active invertase. Kopeloff and Kopeloff²¹ reported a long list of mold fungi from sugar. Many of the common varieties, including those which verge into the yeasts, were isolated. Van der Bijl²² isolated four varieties of fungi and three bacteria from samples of sweating South African sugar. The fungi included *Aspergillus*, *Stemphylium*, *Sterigmatocystis*, and *Hormodendron cladosporoides*. With the exception of *Stemphylium* all were capable of growing in sugar solutions of 63° Brix. Tubes containing inoculated solutions were placed in boiling water for 15 minutes which was sufficient to destroy the organisms. The bacteria seemed to belong to the subtilis-mesentericus group. This was indicated by their thermal resistance, ability to form gum, and their low nutritive requirements. Browne²³ isolated four organisms from Cuban sugars, *Torula communis*, *Monilia nigra*, *Monilia fusca*, and *Bacterium invertens*. Browne mentioned a number of possible sources of undesirable organisms in sugar.

Yeasts. Some difference of opinion exists over the significance of these fungi. Owen believed them to be of minor importance. Tempany and D'Emmerez de Charmoy,²⁴ however, believed them to be very important as spoilage organisms. The term yeasts will be loosely applied here to include fungi which are like yeasts. Jorgensen²⁵ reported *Torulæ* in several refined sugars. Owen²⁰ isolated 17 cultures of *Torulæ* as well as *Schizosaccharomyces octosporus* from sugar. In general, the forms isolated seemed to be without significance in the sugar industry.

Torulæ do bring about some change in the sugar. Browne²³ mentioned the odor of esters formed where sugar was stored. *Torulæ* bring about a reduction in the content of reducing sugars and a corresponding increase in polarization.

Owen²⁶ observed an antagonistic action between molds and *Torulæ* in sugar. When the latter organisms were present, the former could not

invert any sucrose. By virtue of these observations, Owen proposed to inoculate sugar with *Torulae* in order to keep down the undesirable fungi.

Bacteria. Many different species of bacteria have been found in sugar. They are abundant in raw sugar and persist through many of the steps in its manufacture. Owen has studied this subject and was probably the first to propose a connection between the number of bacteria and deterioration.

Deterioration of Raw Cane Sugar in Storage. An account of the nature of raw sugar it is susceptible to attack by various microorganisms. Owen²⁶ observed most of the bacteria in raw sugars to be sporeformers having many characteristics of members of the *subtilis-mesentericus* group. Greig-Smith²⁷ isolated a bacterium to which he gave the name *Bacillus levaniformans* because it formed a gum-like substance. Owen classified the organism as a *Bacillus subtilis*-like species. In an investigation conducted by Tempany and D'Emmerez de Charmoy²⁴ on factors involved in spoilage of raw sugar in Mauritius, moisture content was found to be very important. Moisture may result from that left in the sugar and that absorbed during storage. Tempany and his colleague quote Lewton Brain and Noël Deer as placing the critical concentration of water at one per cent which, if exceeded, will allow development of spoilage microorganisms. Tempany and D'Emmerez de Charmoy described the deterioration in Mauritius as follows:

The bags of sugar appear to sweat, which feature is usually the first to call attention to the deterioration. Examination of the sugar from such bags showed that it was damp and sticky, and in the later stages became liquefied and sirupy. Tempany and his collaborator stated that deterioration usually began in the outermost layers of sugar in the bags and proceeded inwards. Those bags which were in position to have contact with sources of moisture, were also the first to spoil.

Tempany and D'Emmerez de Charmoy²⁴ examined sugar from deteriorated bags bacteriologically. Three types of fungi were found to be present—*torulae*, molds, and bacteria. Contrary to statements of Kopeloff and in agreement with those of Amons, there seemed to be no relation between the number of microorganisms and the degree of deterioration. It was believed that *Torulae* were more responsible for deterioration of sugar than were other fungi. The species studied by Tempany and D'Emmerez de Charmoy had the following characteristics:

“On agar, containing 50 per cent of sugar, the colonies are only visible with a lens 48 hours after inoculation. These colonies are sometimes of the same size, and sometimes of two different dimensions. Those included within the agar are hardly visible to the naked eye, whilst those growing on the surface reach a diameter of .3 to .5 mm. They are at first transparent but later on become almost opaque. Under a low power of the microscope, the colonies are rounded and somewhat granular in appearance. When examined with direct light they are white and absolutely opaque.

“Under a high power the *Torula* is seen to affect two forms—a giant and a rounded one, the small form being about half the size of the large. The small cells are always

27. Greig-Smith. 1901. Linn. Soc. N. S. Wales, Proc. 26, 602.

found in much greater numbers, and are less regular in shape, being somewhat ovoid or acuminate at one end. They vary in diameter from 2.6μ to 7μ with an average diameter of 4.5μ to 5μ . The granulations are numerous and exhibit very rapid vibrating motion. Budding is rather scarce although apparent signs of some are conspicuous. There are never formed strings of any appreciable length.

“In sugar solutions, with or without the addition of nutrient media, and whether grown in pure culture or not, the cells are much smaller than on agar, more transparent, and show scarcely any vacuoles.

“When stained with Grubber’s medicinal pure Methylene Blue, the plasma takes a pale blue color and the metachromatic corpuscles stain pink or darker if the time of staining is prolonged.

“In 10 per cent sugar solutions the growth of the *Torula* is less rapid than it is in 50 per cent solution. Turbidity is not noticeable before 48 hours, after which the ferment begins to settle, the liquid becoming clear again after a few days. A fair amount of sediment is obtained. Effervescence is never produced; only a few bubbles of gas escape during fermentation and this never before 48 hours after inoculation.

“On sweet potato, the organism grows readily and forms a rather thick white shiny layer which spreads over nearly the entire surface of inoculation, without however covering the other sides of the slant.”

It was believed that the sugar became infected with the spoilage organisms between the centrifuge and the bag. The Mauritius sugar was said to be practically sterile. Tempany and D’Emmerez de Charmoy believed it to be an impossibility to keep sugar sterile and prevent all deterioration. While they made cautious statements, it was suggested that the size of the grains might have something to do with spoilage.

Less has been done on the microorganisms which may destroy beet sugar. Mares²⁸ found various fungi and yeasts. Included were species to which the names *Aspergillus betae* and *Penicillium candido-roseum* were given. These fungi were especially common on the beets. Spores were hardy and survived various processes involved in extraction of the sugar and were present in the finished sugar. One species of yeast fermented sucrose very rapidly.

Microbiology of Refined Sugar. Knowledge of the microbiology of refined sugar has been greatly stimulated by investigations on the origin of spoilage bacteria in canned foods. Earlier investigations on the subject were concerned especially with the microorganisms which were deteriorating finished sugar by fermentation or inversion.²⁹ Attention was first called to this problem during the 1925 packing season when a serious spoilage of canned peas was reported to the National Cannery Association. Examination of spoiled cans by Cameron, Williams, and Thompson³⁰ revealed the presence of both “swells” and “flat-sours.” During the next packing season, in 1926, a laboratory was established at the factory where the spoilage had occurred during the previous season, in order to make a thorough investigation of the source of the thermophilic spoilage bacteria. Results soon showed that contamination occurred mainly in the factory either from machinery or ingredients added to the cans. When

the brine was placed under suspicion, the several ingredients were examined separately. Water and salt contained no thermophilic bacteria while sugar was always positive for their presence. It was then necessary to show that other samples of sugar also contained these canned-food spoilage bacteria. Cameron and Williams³¹ believed that all cane sugar contained them in variable numbers. In some samples the number was as high as 100 spores per gram. Thermophilic anaerobic bacteria were commonly found but those causing sulfide spoilage were somewhat uncommon. Samples of beet sugar were quite free from thermophilic bacteria causing flat-sour spoilage; thermophilic anaerobes (spores), however, were more prevalent in beet sugar than in cane sugar. Beet sugars contained no sulfide-spoilage bacteria. James³² confirmed the work of Cameron and Williams in examination of 197 samples of commercial sugars. Aerobic bacteria, thermophilic anaerobes, sulfide-spoilage, and flat-sour-producing bacteria were found to be present. Spores of flat-sour-producing bacteria were abundant. These results caused considerable controversy. Ingersoll³³ was reluctant to believe that refined sugars were as contaminated with spoilage bacteria as reported. He claimed that Cameron and Williams had reached false conclusions in their investigation of the 1926 outbreak of spoilage referred to above. Ingersoll argued that since canning factories had operated for a long time without undue spoilage traced to sugar, sugar could not have been the source of thermophilic bacteria. On the other hand, Bigelow³⁴ and Williams³⁵ each expressed his belief that certain sugars could be incriminated. Cameron³⁶ also took issue with Ingersoll who later apparently accepted the situation. This indicated to Cameron and Yesair³⁷ that plant equipment was not always the sole source of spoilage microorganisms. They reported as many as 2,000 spores of flat-sour-producing bacteria in some sugar. Even though a canner had sterile equipment he would still be marketing a non-sterile product. This would lead to spoilage if his cans were not adequately cooled.

This condition was not limited to American sugars because Homans³⁸ found all three groups of spoilage bacteria in European sugars. More sulfide-spoilage bacteria were found in them than in American sugars. Owen and Mobley³⁹ suggested that attention be given to other bacteria in sugar than the thermophiles. They believed that nonacid-producing thermophiles might also be significant.

The results just discussed prompted sugar refiners to attempt to produce more bacteriologically satisfactory sugars. The sources of infection had to be determined and methods found to prevent development during manufacture. The problem was studied by Cameron and Bigelow,⁴⁰ Owen

and Mobley,⁴¹ and Calton.⁴² Calton summarized the information as far as the sugar mill is concerned:

1. Filtration plays one of the most important roles in removal of thermophiles and thermophilic spores.
2. Accumulation may occur before and after filtration.
3. Crystallization, although less effective than filtration, excludes a large degree of contamination from the sugars.
4. Contamination is confined to the crystals' surface and is greatest in clumps of crystals.
5. Contamination of sirups bears no relation to purity.
6. Flat-sour thermophiles can grow in concentrations as high as 40 per cent raw sugar sirup; growth and acid production are rapid in concentrations up to 25 per cent.

Owen and Mobley found that the microorganism content of sugar was quite variable from month to month, the heaviest infection occurring in April and the lowest in September. This may be due partly to humidity as suggested by King and Suerte.⁴³ That sugar refiners were able to cope with the situation is proven by many results of investigations since the above experiments were made. Great improvement is evident.

Sugar of foreign manufacture contains the same general types in variable number. McMaster⁴⁴ and Barton⁴⁵ found them in English sugars. These sugars did not seem to be as heavily seeded as American and French sugars. Twenty samples of Formosan sugar, examined by Hirabayashi⁴⁶ contained not over 100,000 bacteria. Fungi were also present.

Beet sugar is quite similar in thermophilic bacteria content to cane sugar. It is prepared from the root of *Beta maritima* which thrives in more northern latitudes than sugar cane. After careful washing the beets are sliced; sugar is taken from the slices by diffusion. A large and varied flora is undoubtedly carried into the diffusors. Orth⁴⁷ reported 20,000 bacteria per milliliter in this water. In view of the fact that the temperature in the diffusors is quite near that which favors bacterial growth, these bacteria may cause significant losses of sugar. Samples from 13 sugar factories in Idaho, examined for thermophilic bacteria by Halversen,⁴⁸ were within the limits established by the National Canners Association.

Detecting and Estimating Numbers of Thermophilic Bacteria in Sugar. As soon as it was established that sugar might harbor bacteria which could cause spoilage of canned foods, methods were developed for detecting them and estimating their numbers. The first statement of such a procedure was made by Bigelow⁴⁹ and Cameron⁵⁰ of the

National Canners Association Research Laboratory in 1931, revisions of which have been published at intervals since then. A recent statement of procedure is as follows:⁵¹

12

SAMPLING

Take $\frac{1}{2}$ lb. samples from each of 5 bags or barrels of shipment or of lot in question. Send these samples to laboratory in clean sealed cans, or other appropriate containers.

(The adequacy of this sampling will vary in relation to size of shipment or lot and if there is any significant variability in the shipment, this fact will become evident, in the majority of cases, thru individual tests on 5 samples.)

13

PREPARATION OF SAMPLE

Place 20 g of sugar in a sterile 150 ml Erlenmeyer flask marked to indicate a volume of 100 ml. Add sterile H_2O to the 100 ml mark. Bring rapidly to boiling, and boil 5 min. Replace evaporation with sterile H_2O .

14

CULTURE MEDIA

(a) *Dextrose tryptone agar*.—For use in detection of flat sour bacteria.

This medium is prepared as a standardized, dehydrated medium and is marketed under the name of Bacto-dextrose Tryptone Agar by the Difco Laboratories, Inc., Detroit, Mich. Because of its standardization, its use in this form is recommended. It may, however, be prepared according to following formula: Tryptone, 10 g; dextrose, 5 g; agar, 15 g; bromocresol purple, 0.04 g; and H_2O , 1000 ml.

(b) *Liver broth*.—For detection of thermophilic anaerobes not producing H_2S (*Cl. thermosaccharolyticum*), putrefactive anaerobes, and other mesophilic anaerobes.

Mix chopped beef liver with H_2O in proportion of 500 g to 1000 ml. Boil mixture slowly 1 hour, adjust to ca pH 7.0, and boil an additional 10 min. Then press boiled material thru cheese cloth and make liquid to 1000 ml. To broth add 10 g of peptone and 1 g of dipotassium phosphate. Adjust reaction to pH 7.0. In tubing, introduce $\frac{1}{2}$ -1" of previously boiled ground beef liver into the tube.

Before using, unless it is freshly prepared, exhaust medium by subjecting to streaming steam at least 20 min., and after inoculation, stratify it with 2-2 $\frac{1}{2}$ " layer of plain nutrient agar (common formula), which has been cooled to 50°.

(c) *Sulfite agar (modified)*.—For detection of thermophilic anaerobes producing H_2S (*Cl. nigrificans*).

Prepare according to following formula: Tryptone, 10 g; Na_2SO_3 , 1 g; agar, 20 g; and H_2O , 1000 ml.

At time of tubing place a clean iron strip or nail in tube. No adjustment in reaction is necessary. Prepare medium at frequent intervals (1 week), and if Na_2SO_3 is used in soln also prepare it at frequent intervals (1 week).

CULTURE TECHNIC

15

DETECTION OF FLAT SOUR SPORES

Into each of 5 Petri dishes pipet 2 ml of the boiled sugar soln. Cover, and mix inoculum with the dextrose tryptone agar. Incubate plates at 55° for 36-48 hours, and to prevent drying of the agar, humidify the incubator. The combined count from the 5 plates represents the number of spores in 2 g of original sugar. Multiply this count by 5 to express results in terms of number of spores per 10 g of sugar.

These colonies are characteristic. A colony is round, measures 2-5 mm in diameter, presents a typical opaque central "spot," and is usually surrounded by a yellow halo in a field of purple. This halo may be insignificant, or missing, where certain low acid-producing types are concerned, or where the plate is so thickly seeded that the entire plate takes on a yellow tinge. The typical subsurface colonies are rather compact and may approach the "pin point" condition.

If there is doubt as to the identity of the sub-surface colonies, a decision can usually be made after observing the nature of the surface colonies. If they show

51. Reprinted by permission from Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists, Fifth Edition, copies of which may be purchased from the Association in Washington, D. C.

reasonable purity of flora, it is safe for practical purposes to assume that the subsurface colonies have been formed by similar bacterial groups. It is emphasized that where the plate is heavily seeded, there may be loss of accuracy as regards counts, and colony structure and size may be atypical. If plates are so heavily seeded as to make counting impracticable, a second sample of the sugar may be plated, dilutions of the original solution being used.

Whether atypical subsurface colonies are flat sour organisms may often be determined by streaking from the colonies to agar plates so that their surface characteristics may be noted.

No immediate significance is attached to the presence of "non-spoilage" thermophiles; i.e., aerobic spore-formers, actinomyces, etc., although when present in large numbers they carry significance with regard to the general bacteriological quality of the sugar. The total thermophilic spore count may be obtained from the dextrose tryptone agar plates.

16

DETECTION OF THERMOPHILIC ANAEROBES NOT PRODUCING H_2S

(Under the conditions stated, thermophilic anaerobes are manifest thru the splitting of agar and the presence of acid. At times a cheesy odor is noted. The method is considered suitable as a qualitative test but quantitatively it provides only a means of rough estimation. The method does not permit expression of results in terms of numbers of spores per unit weight of sugar.)

Divide 20 ml of the sugar soln approximately equally among 6 liver broth tubes and stratify the liquid medium with plain nutrient or yeast water agar. After agar has solidified, preheat to 55° and incubate at that temp. for 72 hours.

17

DETECTION OF THERMOPHILIC ANAEROBES PRODUCING H_2S (SULFIDE SPOILAGE ORGANISMS)

(In sulfite agar the sulfide spoilage organisms are detected thru the formation of characteristic blackened spherical areas. Owing to solubility of H_2S and its fixation by the iron, no gas is noted. Certain of the thermophilic anaerobes (not producing H_2S), methods for the detection of which precede, give rise to relatively large quantities of H , which splits the agar and reduces the sulfite, thereby causing general blackening of the medium. This condition, however, is readily distinguishable from the restricted blackened areas mentioned previously. The blackened areas may be counted to obtain quantitative results.)

Divide 20 ml of the sugar soln approximately equally among 6 freshly exhausted tubes containing the sulfite agar. Incubate at 55° for 72 hours.

18

REPORTING RESULTS

Report flat sour and sulfide spoilage results as number of spores per 10 g of sugar. Report thermophilic anaerobes (not producing H_2S) as number of tubes positive and number negative in the following manner: + + + — — —.

Microbiology of Refined Starch. The role of sugar as a source of spoilage bacteria in canned foods prompted investigations on starch which is also added to some foods, such as cream-style corn. Cameron⁵² and Clark and Tanner⁵³ found spoilage bacteria in starch and studied methods for detecting them. The latter used the method proposed by the National Canners Association with a few modifications. Analysis of 20 samples of starch confirmed results of experiments by Owen and Mobley⁵⁴ who found an average of 131 flat-sour-producing spores; 50 per cent of the portions from each sample contained spores of thermophilic anaerobes and 33 per cent sulfide-spoilage organisms. Clark and Tanner found an average of

52. Cameron. 1937. Food Indus. 9, 182-183.

53. Clark and Tanner. 1937. Food Research 2, 27-39.

54. Owen and Mobley. 1932. Ind. Eng. Chem. 24, 1042.

193 flat-sour-producing spores; 50 per cent of the portions were positive for thermophilic anaerobes and only 5.5 per cent of the samples showed sulfide spoilage bacteria.

Owing to the thickening properties of starch Clark and Tanner found that the method given above for sugar analysis was impractical without modification.

Clark and Tanner's⁵⁵ Procedure for Determining the Number of Spoilage Microorganisms in Starch. This procedure is based on the one given above for sugar examination.

Preparation of Sample: Ten grams of starch are weighed into a sterile flask. Enough water is added to make up to 100 grams. This mixture is thoroughly stirred and pipetted into the media for detecting the various groups of organisms.

Detection of Flat-Sour Spores: Twenty ml. of the starch suspension are pipetted into 100 ml. melted dextrose brom-cresol-purple agar or dextrose tryptone brom-cresol purple agar, the mixture being stirred as the starch suspension is added. This agar starch mixture is then heated with frequent shaking until the starch flows, and is then placed in the Arnold sterilizer for 30 minutes with occasional shaking. Place equally among six Petri dishes. Incubate at 55°C.(131°F.) for 36 to 48 hours.

Thermophilic Anaerobes: Twenty ml. of starch suspension are distributed equally among six tubes of liver infusion broth which have been previously heated to 100°C. (212°F.). After reheating and agitating to distribute the starch thoroughly and prevent excess foaming, they are placed in the Arnold sterilizer for 30 minutes, cooled and stratified with plain agar. They are then incubated at 55°C.(131°F.) for five days.

Sulfide Spoilage Spores: Twenty ml. of starch suspension are distributed equally between six tubes of melted "sulfite" agar. The medium and starch are shaken thoroughly to distribute the starch and then heated in the Arnold sterilizer for 30 minutes. After heating thoroughly agitate, allow to harden, and incubate for five days at 55°C.(131°F.).

In order to determine whether these procedures were capable of giving comparable results in different laboratories, Cameron⁵⁵ submitted to 21 laboratories four samples of sugar representing varying degrees of contamination. Results indicated that the method was satisfactory. A few borderline samples gave trouble.

Standards for Sugar and Starch. Bigelow⁴⁹ included the National Canners Association standards for sugar in the report of analytical methods for its examination. Owen and Mobley⁵⁶ criticized these standards because they included only thermophiles. Since the microbial flora of refined cane sugars includes mesophilic and thermophilic sporeforming bacteria, yeasts, and molds, they believed the presence of any of these groups in large numbers was objectionable. Sugars are used in many ways, as in soft drinks, where a heavy microorganism contamination is undesirable. They proposed the following in addition to the National Canners Association standards for thermophiles.

1. The percentage of mold infection in any lot of sugar should not exceed 20.
2. Number of mold spores should never exceed 10.
3. Not more than 20 per cent should contain viable yeast cells.
4. Maximum of 50 yeast cells per gram.

55. Cameron. 1940. Assoc. Official Agr. Chem. J., Aug., 1940, 608-613.

56. Owen and Mobley. 1935. Facts About Sugar 30, 451-452.

5. Maximum number of bacteria other than thermophiles (already controlled) should not be over 50 and the maximum total count should be 100.

Owen and Mobley's standards have not received wide acceptance, especially by the National Canners Association, which still uses the following standards for thermophilic bacteria:

Total Thermophilic Spore Count: For the five samples examined there shall be a maximum of not more than 150 spores and an average of not more than 125 spores per 10 grams of sugar or starch.

Flat-Sour Spores: For the five samples examined there shall be a maximum of not more than 75 spores and an average of not more than 50 spores per 10 grams of starch or sugar.

Thermophilic Anaerobes: These shall be present in not more than three (60 per cent) of the five samples, and in any one sample there shall not be more than four (65 per cent) positive tubes.

Sulfide-Spoilage Spores: These shall be present in not more than two (40 per cent) of the five samples and in any one sample to the extent of not more than five colonies per 10 grams. This is equivalent to two colonies in the six tubes.

Effect of Storage on Thermophilic Bacteria in Sugar. Since this might be one way of meeting the problem if storage resulted in the death of spoilage bacteria, several bacteriologists analyzed stored sugar at intervals. Hall⁵⁷ did observe decrease in these spoilage bacteria in stored refined beet sugar. While the number of spoilage bacteria exceeded the standards in some cases, storage for several months often raised the quality to canning grade. In more work in which beet sugar was again used, Hall observed that thermophilic food-spoilage in beet sugar stored in paper, burlap, toweling, and glass containers generally decreased in numbers during storage for eight and 20 months. The type of container did not seem to influence survival of organisms in sugar during storage. Decreased spore counts probably resulted from dehydration caused by drying of sugar during manufacture or from the presence in sugar of hygroscopic impurities. Hall and Keane⁵⁸ found that many of the spores (47.8 per cent) of *Bacillus stearothermophilus* in sugar could be killed by ultraviolet light (2537Å). Hall's results were confirmed by Clark and Tanner, Jr.²⁹ Ten samples of sugar used in previous experiments were examined after six months' storage in sealed tin cans. The original counts on these samples were all within the limit set by the National Canners Association, ranging from 50 to 75 thermophilic flat-sour spores per 10 grams of sugar. The average for the 10 samples was 70. After storage no thermophilic flat-sour organisms could be isolated from three of the 10 samples. Counts ranged from 0 to 30 with an average of 15, or a reduction of from 40 to 100 per cent, the average reduction being 75 per cent. Thus the bacteriological quality of this sugar was improved by storage. An increase in the number

57. Hall. 1939. Food Research 4, 259-267; J. Bact. 35, 75.

58. Hall and Keane. 1939. Ind. Eng. Chem., 31, 1168-1170.

of spores never was observed. No attempt was made to determine the factors which cause the decrease.

The significance of bacteriological examination of and standards for sugar and similar substances is indicated by results which have been published in annual reports to the Research Committee of the National Canners Association. Extensive outbreaks of spoilage in certain canned foods have been proven to have been caused by contaminated sugar. To show the significance of sugar in canning Cameron and Yesair⁵⁹ packed three lots of corn as follows: one containing no sugar, the second with sugar considered suitable for canning, and the third with unsuitable sugar highly contaminated with thermophilic bacteria which spoil canned foods. The following results were secured:

*Spoilage in No. 2 Cans of Corn Due to Presence of
Thermophilic Bacteria in Sugar*
(After Cameron and Yesair, 1931)

Process at 121.1°C.(250°F.)	Per cent spoilage in corn with		
	No sugar	Sugar A	Sugar B
70 minutes.....	0	0	95.8
80 minutes.....	0	0	75.0
90 minutes.....	0	0	54.2

Sugar A—Suitable for canning nonacid products. “Flat-sour” count, 60 spores per 10 gms. of sugar.

Sugar B—Unsuitable for canning nonacid products. “Flat-sour” count 2,500 spores per 10 gms. of sugar.

Such results indicate the importance of using suitable sugar in canning non-acid products. Cameron and Williams⁶⁰ reported more convincing results on this subject.

MOLASSES AND SIRUPS

Many different kinds are available on the American market. They vary in quality from those which are by-products in the sugar-refining industry to those which are prepared from high-grade saccharine materials for special purposes. Much trouble has been caused by deterioration of molasses and sirups in barrels. In order to prevent such deterioration in sirups to be used on the table, they are processed in tin and glass containers.

While concentrated sugar solutions may function as preservatives, they are not sufficiently reliable to make it unnecessary to add any other preservative. Usually heat in addition is used. The sirups themselves are subject to spoilage by microorganisms. The raw sirups contain a wide variety of microorganisms among which are various yeasts. Hall, James, and Nelson⁶¹ isolated *Zygosaccharomyces nussbaumeri*, *Zygosaccharomyces major*, and *Clostridium saccharolyticum* from cured Barbados molasses.

61. Hall, James, and Nelson. 1937. J. Bact. 33, 577-585.

Canning of Molasses and Sirups. The problems encountered in canning sirups are probably simpler than those encountered with vegetables. The raw material may be highly contaminated with many microorganisms which possess, in most cases, quite low heat resistance. This is especially true for yeasts which cause fermentation of sugar solutions. While these organisms possess low heat resistance according to the usual methods for determining it, they are frequently quite resistant when heated in sirups. It is known that heavy sirups are difficult to sterilize by heat. Much more heat is required to destroy microorganisms in sirups than in water. Rahn ⁶² showed this with yeasts. Since then others have confirmed it, using bacteria. Owen ⁶³ made the same observation when studying causes of spoilage of canned sirup and molasses. Cultures in heavy sirup were reported to be more resistant to heat than in low concentration sirups. He also reported greater heat resistance in corn than in cane sirup. Further information on this subject is given in other places in this book.

Spoilage of Canned Sirups. This may be caused by both bacteriological and chemical processes. Microorganisms involved are those which can survive the processes given canned sirups and develop in heavy sugar sirups. Many cans of swelled cane molasses and mixtures with corn sirup were examined by Owen.⁶³ Even though the characteristics of the spoilage might have suggested fermentation by microorganisms the cause in many cases was not microbial. *Torulae* were found to be the cause of fermentation spoilage. Thermal death times were determined by inoculating tubes of sterile cane sirup with a platinum loopful of growth from an agar slant culture. These tubes were heated in a water bath for varying lengths of time at different temperatures. The tubes were then incubated to permit viable cells to develop. Two of the cultures were found to be more heat resistant than the others. One withstood 76.6°C.(170°F.) for five minutes and the other 79.7°C.(175.5°F.) for 2.5 minutes. Owen then classified his cultures on the basis of their heat resistance, the variation between the two end groups being —3.8°C.(25°F.). Yeasts were observed to decrease progressively in numbers in sirup in which fermentation had occurred. This was shown to be due to carbon dioxide, resulting from fermentation.

The other type of spoilage to which canned sirups are especially susceptible is what Owen ⁶³ called "spontaneous decomposition." It is to be distinguished from true fermentation by yeasts, although living yeast cells may be present in small numbers. A complicating factor is that composition of the gas is about the same in both cases. German technologists called this deterioration "Schaumgärung" or "frothy fermentation." Lueck ⁶⁴ said it was especially common in such products as canned sirups, malt extract, and certain fruits packed in sirups. In general, it has all the evidences of bacterial spoilage but no bacteria.

Development of molds on the surface of sirups in bottles has caused some trouble. Investigation of one sirup packing plant by Ayers and

Barnby⁶⁵ revealed the necessity of filling bottles with hot sirup at a temperature of at least 87.7°C.(190°F.), then sealing at once with cork shells and glass stoppers which have been steamed for 20 minutes at atmospheric pressure. Following sealing, the bottles should be laid on their sides in order that the neck and stoppers will be subjected to as high a temperature as possible. Ayers and Barnby gave curves showing the rate of cooling of sirups in bottles. The temperature and time required to destroy mold spores in sirup was 73.8°C.(165°F.) for five minutes for the conditions under which they worked.

Maple Sugar and Other Products. This carbohydrate is secured from the genus *Acer*, the sap of which is collected after tapping and concentrated by heating. The sap contains from two to three per cent of sucrose with traces of invert sugar. During the early part of the season the sap is clear and sweet, but as the season progresses, especially at the end, it becomes cloudy and may possess bitter principles. This is often called green sap and does not make good sirup or sugar. Besides the content of sucrose, sap contains other bodies which function in supplying the tree with food.

Great improvements have been introduced into the manufacture of maple sugar. Introduction of the evaporator allowed concentration of each day's run of sap, giving a better and clearer sugar and sirup, since the older boiling method made it necessary to hold the sap from large runs until it could be boiled down in the pan. This gave time for the development of bacteria.

The effect of microorganisms on the keeping quality of sap was studied by Edson.⁶⁶ He sterilized bottles of sap by the intermittent method and kept it for months, the flavor remaining unchanged during that time. That which was not sterilized became cloudy and soured very quickly. Edson carefully collected sap under sterile conditions and stated that the souring of sap was not due to auto-decomposition but to the ingress of extraneous organisms; sap collected under aseptic conditions remained sterile. Souring of sap was found to be due to many common bacteria, a few yeasts, and molds.

Sour Sap. This type of spoilage probably includes all decompositions which do not have pronounced characteristics such as a strong color or strong odor. Chemical composition of sap makes it an ideal medium in which microorganisms develop. On nutrient agar, Edson found as many as 141,420,000 bacteria per milliliter in sap. In sweet maple sap the number was much lower. Utensils were found to be important in spreading infection.

Stringy Sap. Edson isolated several organisms which caused a stringy consistency when inoculated into sterile sap. The causal organism was named *Bacillus aceris* since it did not seem to possess characteristics similar to any other described organism. It was capsulated and to this its ability to cause ropiness may be attributed.

Green Sap. Sap which possessed a greenish or brownish-green color was found to contain bacteria of several different types. The organisms were subjected to very careful study later by Edson and Carpenter⁶⁷ and found to be members of the *Pseudomonas fluorescens* group. This type of sap is commonly called "buddy" sap.

67. Edson and Carpenter. 1912. Vermont Agr. Expt. Sta. Bull. 167.

since it is believed by some to be related to the development of the tree in the spring. The green color, however, is due to microorganisms and not to any natural process in the tree.

Red Sap. This color was imparted to sap by bacteria which formed a red pigment. They were said to be widely distributed in the sugar woods. Along with these organisms were yeasts and yeast-like fungi.

Standard maple sirup keeps quite well but it must have between 65 and 67 per cent sugar solids. Such sirup will weight 11 pounds to the gallon. When sugar content exceeds this amount crystallization may occur. Maple sirup spoilage has been shown to be caused by several types of microorganisms. Fabian and Buskirk⁶⁸ isolated bacteria from the sap of *Acer saccharum* which, when inoculated into sterile sap or into dilute maple sirup, produced ropy maple sirup upon concentration of the sap to the consistency of sirup. Since these bacteria were isolated from the sap from which the ropy maple sirup was produced in the sugar bush, they were considered responsible for the condition. Morphological, physiological, and cultural characteristics of the bacteria responsible for this condition, corresponded in all essential details to those of *Aerobacter aerogenes*. Addition of acetic acid sufficient to cause approximately the acidity found in fermented sap did not influence the consistency of the evaporated sap. The addition of a similar quantity of lactic acid did influence the consistency of the sirup. Neutralizing the acidity of fermented sap somewhat reduced the ropy condition of the concentrated sap.

Yeasts were found to cause fermentation of maple sirup by Fabian and Hall.⁶⁹ On the basis of morphological, cultural, and physiological characteristics, they were divided into seven groups as follows: *Saccharomyces aceris-sacchari*; *Saccharomyces behrensianus* (Behrens) Klocker; *Saccharomyces monacensis* Hansen; *Zygosaccharomyces mellis* Fabian and Quinet; *Zygosaccharomyces barkeri* (Barer) Sac. & Syd.; *Zygosaccharomyces japonicus* Saito; and *Zygosaccharomyces nussbaumeri* Lochhead & Heron. Vegetative cells were killed in nutrient broth at 55°C.(131°F.) in five minutes and in maple sirup in five to 10 minutes at 60°C.(140°F.). In most cases ascospores were killed in nutrient broth at 65°C.(149°F.) in five minutes and in maple sirup at 75°C.(167°F.) in five minutes. The moisture content of freshly made maple sirup was 26.3 to 36.5 per cent. Samples of fermented maple sirup contained 32.7 to 34.6 per cent moisture.

Canned Maple Sirup. Maple sirup has been sold in tin cans for many years but the cans were never sealed as cans for other foods have been. After studying the problem Fellers⁷⁰ believed there should be no difficulty. Plain cans kept maple sirup about as well as did enameled cans. Fellers found, for instance, that U. S. Grade No. 1 sirup, which has a light amber color, was still classified in the same grade after eight months of storage. There was a tendency for heated sirup to become darker. Processing in boiling water produced a slight darkening which was not serious. One of the significant observations by Fellers, was that if the sirup is filled

into the cans at 93.3°C. (200°F.) or above, no further processing was necessary. As small headspace as possible should be left in the can in order to reduce the amount of free oxygen present.

Spoilage of Maple Products by Molds. Development of molds in maple products, if allowed to continue, soon results in off-flavors. Fellers⁷¹ reported that *Aspergillus* species grew well in tub maple sugar containing from five to 12 per cent of moisture. Such maple sugar often becomes moist and semiliquid owing to the inverting action of invertase on a part of the sucrose. The "sweating" or runny condition of maple sugar was attributed by Fellers to this action. Both mold growth and invertase action are accelerated by high temperatures. Mold spores are unable to survive the concentration methods used in making maple sugar and probably get into the sugar from utensils after it has been made. Fellers recommended the Howard method for determining whether molds are present in the sugar.

HONEY

Honey is probably the first sweetening agent used by man. It is frequently mentioned in the scriptures and the types of yeast cells found in bread from Egyptian tombs indicate that honey was probably used in its manufacture. Undiluted honey is quite resistant to decomposition by ordinary microorganisms. If it is diluted with water some microorganisms may start to decompose it. As Fabian and Quinet⁷² suggested, organisms take up their abode on the surface where perhaps water from the air has diluted the honey. These organisms also become accustomed to a higher concentration of sugar and in time are able to induce an active fermentation.

Microorganisms in Honey. While comb honey may contain a few microorganisms, White⁷³ and Sackett⁷⁴ have reported it to be sterile most of the time. The former, according to Sackett, isolated *Bacillus A* (*Bacillus mesentericus*), *Bacterium acidiformans*, and *Saccharomyces rosens* from combs. Sackett examined comb honey from many different sources and found it to be uniformly sterile.

Schweizer⁷⁵ found practically all Swiss honeys to be free from bacteria, as were also several of French origin. Many Swiss honeys as well as several foreign brands were examined bacteriologically. It was concluded that a bacteriological examination does not show the origin of the honey. Fehlmann⁷⁶ reported the presence of *Pleurococcus vulgaris*, a green alga, in honey in Switzerland. This organism is apparently able to withstand the concentrated carbohydrate solution in honey. Sartory and Moreau⁷⁷ examined honeys from various sources and found *Bacillus subtilis*, *Bacillus megaterium*, *Bacillus aerophilus*, *Sarcina lutea*, *Micrococcus radiatus*, *Staphylococcus pyogenes*, *Penicillium glaucum*, *Rhizopus nigricans*, *Sac-*

charomyces cerevisiae, *Mucor racemosus*, *Aspergillus gracilis*, *Sterigmato-cystes nigra*, pink yeast, etc. Among various microorganisms a yellow bacillus was isolated which produced a coloring matter at an optimum of 30°C. (86°F.) slightly soluble in absolute alcohol. Its color was changed to a yellow-brown by the addition of alkali, but when acidified it resumed its original shade. The bacillus was placed in a class with *Bacillus luteus* and *Bacillus flavus*.

Longevity of Microorganisms in Honey. This has been investigated mainly for pathogenic bacteria. One investigator was prompted to study the problem because he saw bees crawling over human excrement. It seemed desirable to know how long objectionable bacteria could survive in honey. Little information if any was available on this question until Sackett⁷⁴ reported results of quite extensive experiments with new fall honey and fall honey six months old. In the former *Eberthella typhosa* survived for only 48 hours. In dilutions above 50 per cent, it was dead after 24 hours. After four days it was alive only in the control which contained no honey. In the second series, *Eberthella typhosa* was not present in the pure honey after 24 hours and was absent from dilutions above 50 per cent in 10 hours. After 24 hours it had disappeared from 30, 40, and 50 per cent dilution; and after 48 and 72 hours it was no longer present in the 20 and 10 per cent dilutions. *Salmonella schottmülleri* was very sensitive. It disappeared from pure honey in 48 hours and from dilutions above 30 per cent in 24 hours. In the second series, it was dead in 24 hours in pure honey and after 10 hours in all dilutions above 20 per cent. *Salmonella paratyphi* in the first series, exhibited about the same resistance as *Salmonella schottmülleri*. It was dead after 24 hours in pure honey and in all dilutions above 30 per cent. *Eberthella dysenteriae* could not survive in pure honey nor in dilutions above 40 per cent after 10 hours. In the second series it was dead after 10 hours in pure honey and had disappeared in five hours from all dilutions above 20 per cent. Sackett's results are somewhat different from what would be expected, for pure honey is a very highly concentrated sugar solution. Sackett discussed the situation as follows:

The failure of the organisms to die out as readily in concentrated honey as in the dilutions was rather interesting. A possible explanation of this suggests itself in the physical state of the sugar particle in the honey. Assuming the honey to have been a saturated solution, and this appears to have been the case, there is a probability that it was a colloidal solution with low osmotic pressure. In such a solution plasmolysis would take place relatively slow. When water was added, as in the dilutions, some of the colloidal sugar passed over into molecular solution, the osmotic pressure increased, and plasmolysis became more active.

Sackett's results were confirmed in general by Schett.⁷⁸ He found that pathogenic bacteria did not survive long times in honey. While Schett did not attribute this to a definite germicidal action, others have said that such action was observed and have described the germicidal substance. Such a substance was said to exist by Prica.⁷⁹ Neither acidity nor sugar content could explain the bactericidal action. The active principle was

78. Schett. 1937. Ztschr. f. Hyg. u. Infektionskrank. 120, 155.

79. Prica. 1938. Ztschr. f. Hyg. u. Infektionskrank. 120, 437-443.

filterable, resistant to sunlight, withstood heating to 90°C.(194°F.) for one hour, but was partially destroyed by boiling for five minutes. Whether it came from flowers or bees was not determined. Prica⁷⁹ carried out his experiments with *Escherichia coli* and *Staphylococcus aureus*. Work by Bahr⁸⁰ also seemed to indicate presence of a germicidal substance in honey. "Linden-tree," clover, and sage honey from New Zealand and California showed greater effectiveness against "Ratinbacillus" (*Salmonella enteritidis*) than manufactured honey. Heat seemed to decrease the strength of the substance.

Fermentation of Honey. Honey is susceptible to fermentation by various microorganisms. These may be incorporated in the honey by the bees or may come from contaminated utensils. In some cases the bees contaminate the honey in the comb with yeasts so that it ferments and disrupts the cells. Bees are known to harbor yeasts. One of the best known organisms in this respect is *Zygosaccharomyces mellis acidi* Richter. The honey from which Richter⁸¹ isolated this yeast had undergone an alcoholic fermentation. Klöcker⁸² isolated *Zygosaccharomyces prioranus* from a bee. White⁷³ isolated several species of yeasts from bees. Ewert⁸³ stated that yeasts were present in honey and could cause spoilage. Nussbaumer⁸⁴ found several species of *Zygosaccharomycetes* in numerous samples of honey, the sources of which were unknown. Fabian and Quinet⁷² isolated 25 yeasts from honey, both normal and abnormal. These investigators put their yeasts into five groups, as follows:

- | | |
|-------|--|
| Group | I. <i>Zygosaccharomyces japonicus</i> , Saito |
| | II. <i>Zygosaccharomyces Barkeri</i> |
| | III. <i>Zygosaccharomyces mellis</i> , Fabian and Quinet |
| | IV. <i>Zygosaccharomyces prioranus</i> |
| | V. <i>Torula mellis</i> , Fabian and Quinet. |

Vegetative cells of *Zygosaccharomyces* were killed at 50°C.(122°F.) for 10 minutes in broth; vegetative cells of *Torulae* were killed at 50°C. in 15 minutes. In honey, vegetative cells of *Zygosaccharomyces* were killed at 60°(140°F.) in five minutes and *Torulae* at 60°C.(140°F.) in 10 minutes. Honey is quite hygroscopic and may absorb enough water to ferment. Fabian and Quinet found the critical concentration to be about 21 per cent. They believed that honey could absorb enough water at the surface to allow fermentation to begin. Yeasts then gradually become accustomed to the higher sugar concentration and eventually grow throughout the honey. Very interesting are the data reported by Lochhead and McMaster,⁸⁵ that sugar-tolerant yeasts were found to be present in all of 191 samples of Canadian honey. The number varied greatly, however, with an average count of 1,000 per gram. Yeast infection was believed to be a factor directly affecting fermentation of honey. Although the yeast count tended

to increase with increasing moisture content, fermentation was not considered to be merely a function of the latter.

At the University of Wisconsin, Marvin⁸⁶ studied the yeasts in fermented honey. Five strains were isolated, all of which were able to grow in concentrated solutions of honey. Marvin reported that undesirable flavor of fermented honey was due to alcohol, nonvolatile acids, and carbon dioxide. Marvin further reported that honey which was to be sold in small containers should be heated to 71.1°C.(160°F.) and sealed while hot. Prompt cooling was advised in order not to affect the color. Unheated honey should be stored below 11.1°C.(52°F.) to prevent fermentation. Marvin believed that crystallization of honey made it more possible for yeasts to ferment it, which was later confirmed by Marvin, Peterson, Fred, and Wilson.⁸⁷ The fermentation process was said to be slow and to extend in some cases over several years. About equal quantities of carbon dioxide and alcohol (rarely over five per cent) together with nonvolatile acids are the chief fermentation products. They stated that fermentation of honey could be prevented by heating it to 71.1°C.(160°F.), pailing while hot, and, after cooling, storing below 11.1°C.(52°F.). Townsend⁸⁸ believed that lower times and temperatures could be used than would be expected.

A number of pure yeast cultures were isolated from fermented honey by Lochhead and Heron.⁸⁹ Early work indicated the presence of osmophilic yeasts which could not develop in low concentration. They showed, in a striking manner, the differences in tolerance to honey of species responsible for fermentation of honey and ordinary species. Four pure cultures of yeasts were isolated for intensive study. Two of them were believed to be new species and were named *Zygosaccharomyces nussbaumeri* and *Zygosaccharomyces richteri*. The descriptions of these two species are given by the authors. In order to determine the possible origin of sugar-tolerant yeasts, Lochhead and Heron examined 34 kinds of flowers commonly visited by bees during a season. Eleven different yeasts which were able to ferment high concentrations of honey were isolated and described. Two of them proved to be identical with types found in fermented honey. Another type was identical with Fabian and Quinet's *Torula mellis*. Examination of the hives for sugar-tolerant yeasts indicated a constant and early infection. Soil from about the hives were found by Lochhead and Farrell⁹⁰ to harbor the above-mentioned organisms. Ordinary field soil is not a primary source of infection of honey, for sugar-tolerant yeasts are not regarded as members of the normal soil microflora. Sugar-tolerant yeasts, in apiary soils, are able to remain viable through the winter in frozen soil, but are cold-enduring rather than psychrophilic. From the soil 166 cultures of sugar-tolerant yeasts belonging to *Zygosaccharomyces* and *Torulae*, were isolated and classified. These were found to represent seven types considered as six species with one subspecies, three being types found in fermented honey.

88. Townsend. 1939. J. Econ. Ent. 32, 650-654.

89. Lochhead and Heron. 1929. Canad. Dept. Agr. Bull. 116.

90. Lochhead and Farrell. 1930. Canad. J. Res. 3, 51-64.

A study of the predominant sugar-tolerant yeasts infecting 163 samples of normal Canadian honey, by Lochhead and Farrell,⁹¹ led to recognition of eight species, comprising the genera *Zygosaccharomyces*, *Schizosaccharomyces*, and *Torula*. The frequency of their occurrence varied greatly, *Zygosaccharomyces dichteri* being by far the most commonly encountered. The yeast predominating originally is not necessarily the most abundant type for fermentation. Analysis of samples fermenting within 14 months showed species of *Zygosaccharomyces* only to be most abundant, while *Zygosaccharomyces richteri*, in addition to being the predominant type infecting a large majority of samples, was able, even in certain cases where it was originally outnumbered, to develop and apparently assume the leading role in fermentation. Later work by Lochhead⁹² in which 128 samples of normal honey were examined, showed the presence of sugar-tolerant yeast in all cases, confirming a previous study of 191 samples. Yeast counts were one to 1,000,000 per gram. The tendency of honey to ferment within one year increased with increased yeast infection. The view that the amount of yeast infection, apart from moisture, is a factor directly affecting fermentation was confirmed. Although the honeys varied in their content of so-called "bioactivator," capable of stimulating the activity of osmophilic yeasts, this factor is not considered significant in affecting the spoilage of honey under practical conditions. Fermentation is conditioned essentially by the moisture and yeast infection of honey, and a zone of probable safety with respect to these factors is indicated.

Heat resistance of strains of yeasts isolated from honey by Lochhead and Farrell⁹³ was determined by Stephens⁹⁴ by heavily inoculating sterile honey. Since investigations had revealed no more than 100,000 yeast cells per gram in Canadian honey, Stephens tried to approximate this number. Owing to ability of some species of yeasts to withstand considerable heat in honey, and absence of any necessity to destroy all living cells, Stephens suggested the term "commercial sterility" for use in honey pasteurization. Based on experimental data, Stephens stated that it would require one hour and 40 minutes to five hours and 30 minutes to reduce the count to less than 10 yeast cells per milliliter at 50°C.(122°F.) depending on the species and the initial inoculation. Curves in Stephen's paper show that rates of death of different species vary greatly. At 60°C.(140°F.) the time necessary to obtain "commercial sterility" would be less than 30 minutes. Stephens believed that to attain "commercial sterility" by flash pasteurization a temperature near 80°C.(176°F.) would have to be used, the exact temperature depending on the time necessary to bring the honey to that temperature.

Effect of Preservatives on Fermentation of Honey by Yeasts. Investigations by Lochhead and Farrell⁹⁵ have resulted in information on this subject. Various preservatives were used, but since sodium benzoate is the

only one in the group which is permitted in foods, only the results secured with it need be given. It was found to exert a repressing effect on the growth of yeasts and to be without effect on the flavor of the honey. Later these investigators reported that in 80 per cent honey solution containing 64 per cent of sugar, .05 per cent of sodium benzoate, calculated as benzoic acid, was the lowest effective concentration for killing the osmophilic yeast, *Zygosaccharomyces nussbaumeri* within 26 weeks. For inhibition of fermentation a concentration of .04 per cent was sufficient. With sodium hydrogen sulfite (NaHSO_3), .02 per cent, calculated as sulfur dioxide, was the minimum lethal concentration as well as the lowest which inhibited fermentation during the same period. The effect of these substances in retarding fermentation by mixed strains of *Zygosaccharomyces nussbaumeri* is increased with increasing sugar concentration. When added to freshly extracted honey .025 per cent of sodium benzoate and .01 per cent of sodium sulfite (Na_2SO_3) were effective in preventing fermentation during storage.

CANDY

Candy is a product which may easily be contaminated by indifferent methods of preparation but especially from insanitary conditions of handling. The prevalent custom of wrapping smaller pieces has contributed to a much safer and cleaner product. The Food and Drug Administration⁹⁶ has studied the conditions which obtain in the confectioner's industry. They recognize that candies may be objectionable owing to improper storage conditions, remanufacture of returned goods, and manufacture from unfit material. The Bureau recognized improper storage conditions as one of the important common sources of adulteration.

Microorganisms in Candies and Confections. The types and numbers are influenced by such factors as microbial content of raw materials, methods of manufacture, and vending. Our information comes mainly from a few investigations, results of which have been published.

Tanner and Davis⁹⁷ investigated the sanitary condition of candies purchased on the open market. Coliform bacteria were not encountered in any of 30 specimens examined. Bacteria in candy were said to be in a dormant condition. Sporeforming bacteria predominated. On account of these facts, candy which might be contaminated by a carrier could be a source of danger. The number of bacteria per gram was found to be variable and probably dependent on conditions in the factory, methods of manufacture, and especially the raw materials and flavors used. As Bachman has reported, Tanner and Davis found a distinct germicidal action in such varieties as cinnamon drops and mint candies. These species have been found to destroy bacteria.

A more comprehensive study of this question was reported by Weinzi⁹⁸ who examined 1,138 specimens purchased on the open market. Coliform bacteria were found on 2.5 per cent of the samples. Many of

98. Weinzi. 1927. Amer. J. Pub. Health 17, 708-711.

these instances occurred with candies containing unsterile ingredients, such as nuts. The bacteria belonging to the coliform group were mostly atypical. Typical *Escherichia coli* or *Escherichia communior* were found but twice in 525 samples. Weinzirl stated that danger of candy carrying disease-producing bacteria can readily be eliminated by sterilizing the materials from which it is made and by using sanitary devices for handling. These data indicate that candy may carry undesirable bacteria and that it should be handled with the same care that is given to other foods. Such was the suggestion of Greaves.⁹⁹ She analyzed 200 samples of candy and found the bacterial content to vary with (1) type of store from which it was obtained, (2) type of candy, (3) wrapped or unwrapped condition, and (4) nature of the centers of the candy. Poorly kept stores, conducted by careless individuals, dispensed candy with a high bacterial content, and in a large percentage of cases acid-producing organisms were present. Sanitary conditions of the store and clerk were more important factors in determining bacterial contamination than type of store. Handmade candies were usually found to be higher in bacterial content than machine-made candies. Soft and nut-containing candies were usually higher in bacterial content than were hard candies and those free from nuts. Careless methods of displaying candies increased the bacterial content. Candies which dry rapidly decrease in bacterial content quite rapidly when exposed to light and air. More bacteria were found in the centers than on the surface. Quite similar results were secured by Ciampi¹⁰⁰ and Driml¹⁰¹ from examination of these products made in foreign countries.

About the same bacteriological condition was found to exist in candies purchased on the American market by Tanner and Snyder¹⁰² during the year 1939. Coliform bacteria were not found in any of the samples examined. Wrapped products usually had fewer bacteria as did hard candies which are heated to high temperatures during manufacture. Those products to which raisins, fruits, and nuts are added may have many bacteria. Tanner and Snyder examined many samples of various kinds of candies for mesophilic and thermophilic bacteria growing aerobically and anaerobically. The chocolate products contained, in general, more microorganisms.

Longevity of Microorganisms in Candy. Cummins¹⁰³ investigated the death rate of different pathogenic bacteria in candy. Information of a general nature was given regarding the importance of the confectionery industry and its sanitary aspects. Only chocolate-coated candies were used. The methods of their manufacture were discussed briefly in so far as they influenced the sanitary quality of the finished product. A few data were given, showing the bacterial content of various raw materials used in the manufacture of chocolates. In the experiments a mixture of sugar, chocolate, and milk powder was prepared. After being sterilized,

portions of this were inoculated with cultures of different types of bacteria. The inoculated portions were stored at approximately 20°C.(68°F.) and samples were taken from them at stated intervals for bacteriological examination.

The organisms used were *Eberthella typhosa*, *Escherichia coli*, *Hemophilus pertussis*, and *Mycobacterium tuberculosis*. A study of the effect of hand and machine methods of dipping chocolates upon the bacterial content showed that in almost every instance machine-dipped chocolates contained fewer bacteria than hand-dipped ones. Little or no increase in the number of bacteria originally present took place in the case of machine-dipped chocolates. In general, it was found that the raw materials, especially chocolate, are the sources of a large number of the bacteria present in chocolate candies. The experiments with *Hemophilus pertussis* showed that within a few hours after inoculation these organisms ceased to be present in the candy. In the opinion of the author, there was little possibility of the transmission of whooping cough by candy infected in the factory. Although the results obtained with *Mycobacterium tuberculosis* were regarded as unsatisfactory, they indicated slight possibility of surviving for a long time in chocolate. After a long period of storage, it was possible to isolate *Eberthella typhosa* from the inoculated candy; the results indicated that there was a possibility of typhoid fever being transmitted by infected candy in case a worker should be a carrier. It was found also that members of the coliform group survived for a long time, and the results of the experiments indicated that after being inoculated into candy these organisms would probably find their way into the body through this source. The death rate of the organisms seemed to be somewhat related to the amount of water present in the candy. In a candy of high water content the bacteria died out faster than in one with low water content.

Longevity studies were also made by Tanner and Snyder,¹⁰² using fondant and fudge. They observed a regular decrease in viable bacteria which were inoculated into fondant and fudge. Since they died faster in the latter, it was believed that chocolate might have had a repression effect on the bacteria which were used. Candies to which nuts and similar fillings were added often contained many bacteria. *Escherichia coli* was not found in any market samples.

Bursting or Explosion of Chocolate Creams. This deterioration of chocolate-coated creams was studied by Church, Paine, and Hamilton.¹⁰⁴ They believed that constitution of the fondant made possible the growth of spoilage organisms. This was described as a cream or a sirup enveloping closely packed particles of microscopic crystals of sucrose and fragments of coagulated egg white. Each sugar crystal was said to have a thin film of sirup about it. The small particles of egg white furnish protein for the bacteria which may be present. Many inoculations were made into fondant and chocolate creams. This work resulted in conclusions that yeasts tolerant of high percentages of sugar in sirup, are capable of caus-

104. Church *et al.* 1927. Ind. Eng. Chem. 19, 353.

ing bursting of chocolate-coated creams and that bursting is primarily due to formation of minute quantities of gas in the cream through microbial activity. The yeasts obtained from exploded commercially-manufactured confections were of different types. Church, Paine, and Hamilton believed that some means must be devised in candy factories to develop a cream containing sirup of high density.

Weinzirl¹⁰⁵ quoted an article in the *Western Confectioner*, July, 1920, by J. P. Hill, as stating that explosion of chocolate-coated candy was due to *Escherichia coli*. Weinzirl found *Clostridium sporogenes* to be the chief cause of the trouble, but that yeasts could also cause it. He could find no evidence that *Escherichia coli* was involved. The source of the infection was found in egg albumen which was being used. Weinzirl¹⁰⁶ stated that sugar itself was the source of anaerobes also. Thirty-three samples were analyzed; anaerobes were reported in 85 per cent of the 330 gram samples tested. Five types of anaerobes were found: *Clostridium sporogenes*, *Clostridium putrificum*, *Clostridium aerofetidum* and two unidentified strains. Sugar seemed to be a source of the organisms causing explosions of chocolate candy. Hill¹⁰⁷ isolated a saccharolytic anaerobe thought to be *Cl. multifermentans* from 11 out of 24 samples of chocolate creams which had spoiled through cracking. The organism was also isolated three times from mazetto cream, a commercial preparation used in confectionery as a foundation for cream fillings, and three times from egg albumen. The inoculation of 15 samples of unspoiled chocolate creams with a pure culture of the organism caused splitting in nine cases. The cultural and morphological characteristics of the organism were outlined. According to Philbrick,¹⁰⁸ one cause of cracked or blown chocolate creams was a facultative anaerobic bacillus capable of fermenting dextrose. The bacillus probably entered through some one of the ingredients, but it was difficult to establish which was the infecting material as the spoilage was often not apparent until the materials had been consumed in the factory process. On the other hand, examination of the molding starch generally showed the presence of the organism. In this manner, the starch acted as a secondary infecting agent long after the original had been eliminated by use. The infected starch should be discarded to effect a complete and final elimination of the infection. Starch was also said to be the source of gas-forming bacteria by Stapp¹⁰⁹ who studied the cause of bursting chocolate-covered confections. Besides molds, sporeforming rods which fermented glucose, fructose, and cane sugar were present.

Paine, Birekner, and Hamilton¹¹⁰ stated that only a small amount of gas was needed to break the chocolate. When this does occur, a sirup exudes through the opening. When considerable gas is formed, the entire center may protrude. They stated that the density of the sirup in fondant

may vary widely, but that it was possible to produce a sirup of sufficiently high density to inhibit the growth of even those yeasts which are tolerant of high sugar concentrations. This is apparently the only alternative since it seems to be impossible to get rid of the undesirable bacteria. Paine and Hamilton¹¹¹ suggested the use of invertase for controlling inversion of a part of the sucrose after the goods are made. It was found that fermentation of even highly sugar-tolerant yeasts could be controlled in a practical manner by increasing the solids concentration of the sirup portion to about 79 per cent with invertase.

CHAPTER 20

MICROBIOLOGY OF FISH AND SHELLFISH

Flesh of various animals which live in the sea has become an important food in most nations. Better methods of preservation are making it possible for inland communities to be supplied with sea foods. Owing to the fact that fish muscle is susceptible to both enzymic and bacterial decomposition, problems of preservation have required much study. Related to these problems of preservation are those of sanitation to insure not only a product which has no gross evidence of decomposition but which is free from contamination with undesirable bacteria. Fishermen try to accomplish these ends by icing the fish immediately after they are caught and handling as carefully as possible. Increased markets resulting to some extent from more satisfactory methods of preservation, have made it necessary to use fishing grounds farther and farther removed. This means longer trips and longer holding periods.

Many fish are now gutted at sea soon after they are caught. Fitzgerald and Conway¹ pointed out that this practice contaminates all surfaces of the opened fish with many bacteria; special care is therefore necessary to hold the fish in good condition. Such surface contamination may be removed by thorough washing and scaling when the fish is filleted. Wash water may contain from one to two parts per million of chlorine to keep the water sterile. Fitzgerald and Conway believed this to be about the only reason for using chlorine in wash water. *Escherichia coli* was not removed from whole fish by soaking in chlorine wash water for two minutes. Scaling and washing removed many bacteria. One gains the impression that sanitation of a plant in which fish is prepared for the market, involves generous use of water and chlorine compounds. Gibbs² reported that on English fishing boats, calcium hypochlorite has been incorporated into the ice used for holding fish. This compound used in this manner was said to have marked germicidal and preservative action. One part in 400 parts of water before freezing seemed to be most active. This compound has also been used as such in the fish industry. Harrison and Sadler³ found calcium hypochlorite in ice to be beneficial in destruction of a fluorescent organism which caused spoilage. Chen and Fellers⁴ prepared sodium hypochlorite electrolytically. Experiments with eulachon (Columbia river smelt) and halibut showed that immersion in sodium hypochlorite containing .6 per cent of available chlorine for five minutes materially reduced the number of bacteria and enhanced the keeping quality. Solutions with less than .2 per cent of available chlorine were ineffective. Eulachon were unaffected as to color, odor, and taste; halibut, however, became yellowish, and attempts to prevent it were negative. Sodium hypochlorite

ice containing .6 to .2 per cent of available chlorine acted like sodium hypochlorite when it melted. Chen and Fellers believed that the use of such ice was beneficial and should have wide application.

Production and distribution of crustacean meats has become a great industry. Hunter⁵ has pointed out how many sources of contamination exist in the picking, handling, and packing which might be dangerous to human beings. Aside from sanitary inspections Hunter favored bacteriological procedures and development of a standard method of procedure. He reported that the Food and Drug Administration accepted the presence of *Escherichia coli* as satisfactory evidence of danger to health. Ordinary cooking, according to Nickerson, Fitzgerald, and Messer⁶ does not eliminate all fecal organisms. Pressure cooking is satisfactory. They found chlorine treatment to be useful for utensils and apparatus.

Sterility of Fresh Fish Muscle. Whether fresh fish muscle contains viable microorganisms is still a debated question despite the fact that it has been studied by many investigators. Harrison, Perry, and Smith⁷ studied the question for haddock, mackerel, and halibut. Their specimens were carefully caught and handled. Using very careful technic, examination of eight fresh haddock indicated the tissue to be sterile. With these conclusions, those of Gee⁸ are in disagreement. Gee removed specimens of muscle from fish under as carefully controlled conditions as possible and was able to culture an aerobic sporeforming organism from fresh muscle. The organism was quite pleomorphic and was believed to have an important share in the breakdown of haddock muscular tissue. Bruns⁹ believed that fish muscle was sterile for several days after death if properly preserved on ice. Browne¹⁰ also reported the tissue of fresh fish to be sterile. Ulrich¹¹ found members of the coliform and *Proteus* groups in fish. Muller¹² could not find bacteria and, consequently, concluded that fish tissue was sterile. Hunter¹³ found the muscular tissue of freshly caught salmon to be sterile.

In view of the fact that Gee reported sporebearing bacteria to be commonly present in fish muscle, and in view of the fact that such bacteria were found to be absent in the slime on market fish, Stewart,¹⁴ also, was prompted to study sterility of fish muscle. Working with eight fish, Stewart was unable to confirm Gee's conclusions. Five of 143 cultures prepared from fish muscle showed growth. These were attributed to contaminated specimens. This seems to be an arbitrary conclusion. Gee¹⁵ published more evidence that muscle tissue of live fish is not necessarily sterile, organisms being obtained from five of 41 fish. On the other hand, Proctor

and Nickerson¹⁶ could find no microorganisms in muscle of freshly caught haddock. These conclusions were based on examination of 120 excised muscle samples from six haddock.

Discoloration of Halibut. This fish is caught in great numbers on the western coast of the United States and Canada and is shipped in the frozen condition to all parts of North America. A defect of this fish discussed by Harrison and Sadler³ is the appearance of a yellow or greenish-yellow coloration in the slime about it or on the fish itself. Examination of the slime under the microscope indicated the presence of many bacteria. Inoculation of sound fish with slime from an infected fish reproduced the abnormality indicating that it was due to growth of microorganisms and was an infection. Harrison and Sadler isolated the organism in pure culture and reported it to be a member of the fluorescent group, members of which are widely disseminated in natural waters. Having proven by isolations from over one hundred halibut from many different boats that this organism was the cause of the trouble, Harrison and Sadler then studied the origin of the organism. It was found to be present in ice used for preserving the fish and on the various objects with which the fish came in contact. Very significant was the observation that halibut from sea water did not harbor these organisms. Harrison and Sadler found that chlorination of the water used for making the ice in the amount of three parts per million killed the organisms. They reported that water from which ice is made should be disinfected in some manner. In a longer report on deterioration of halibut Harrison¹⁷ stated that discoloration was most marked in the slime of the dead fish. This is so rich in nitrogen that it is an excellent food for bacteria. Stained films from this slime showed various microorganisms. When discolored slime was streaked on sound whitefish, characteristic discoloration was produced. The causal microorganism proved to be *Pseudomonas fluorescens*. It was isolated from upland surface lake water, neither filtered nor chlorinated, which was used for making ice. The organism was said to penetrate the skin of the fish where it caused putrefaction, *Pseudomonas fluorescens* was not isolated from sea water nor from fish freshly caught until they had been landed aboard the boat. The sole primary source was said to be the ice or ice water from which ice was made. Some 15 other species were identified by Harrison; they were not especially related to fish-spoilage problems. When the skin of halibut was inoculated with certain marine chromogenic bacteria, Bedford¹⁸ found that the flesh became discolored as well as sour in 10 days at 0°C. (32°F.) Later he reported results of investigations of discoloration of stored fresh and frozen fish. Discolorations of special interest to the industry are yellowing and reddening or "rusting" of stored fresh salmon. Some of these defects are bacterial in origin but chemical causes may also be involved. The objectionable bacteria may be killed by disinfection of the fishing boats, thorough cleaning of the fish, and proper handling.

Complaints that freshly caught salmon had an earthy taint prompted Thaysen and Pentelow¹⁹ to look into the matter. Actinomyces species were found to be responsible. They were abundant in the water from which the fish came and reached the blood stream of the fish after entering through the gills. The compound which caused the taint could be distilled from cultures.

Microbiology of Fish. Owing to the fact that fish may be caught in unclean waters as well as to the fact that they may undergo rapid decomposition, many investigations have been carried out to learn more about their microbiology. New methods of preservation have had to be evaluated to determine their effect on microorganisms. The subject was reviewed by Griffiths.²⁰ In an investigation of fish purchased on the open market in Aberdeen, Stewart²¹ concluded that the longer the time between catching and marketing, the greater was bacterial contamination. Microscope examination of the slime showed such a heterogeneous flora, that Stewart was prompted to study the relation of this flora to keeping quality and spoilage. The bacteria which were found belonged to the groups found in water, *e.g.*, *Achromobacter*, *Flavobacter*, *Pseudomonas*. Sporebearing bacteria were almost entirely absent. Coliform bacteria were not found, even though some of the fish which were examined came from polluted waters. Anaerobic bacteria were also not found in slime of haddock but were present in small numbers in the intestines. They appeared to belong to the nonspore-forming genus *Bacteroides*. The anaerobes in the intestines proved to be *Clostridium sporogenes* and *Clostridium putrificum*. Shewan²² reported isolation of *Clostridium tetani* from the intestines of fish for the first time.

An extensive study of the microbiology of fresh salt-water fish was the subject of a study by Harrison, Perry, and Smith.⁷ Their work was more closely concerned with haddock, mackerel, and halibut, but in addition, a few other fish were examined. They first studied the effect of freezing. Fish were kept at 10°C. (50°F.), 15°C. (59°F.), and 20°C. (68°F.) for six and 24 hours, and bacteriological examination was made at the end of these times. The results indicated that bacteria increase slowly at 10°C. (50°F.) but somewhat more rapidly at 15°C. (59°F.). After four months' storage, the number never exceeded 600 per gram and in a number of instances was considerably less. Eviscerated fish had a higher bacterial content.

In an investigation of the bacteria causing spoiling of haddock by Gee,⁸ isolations were made from fish stored at room temperature for a week or so, after which time the flesh was foul. An organism was isolated which showed considerable pleomorphism. It was believed to be *Bacillus vulgatus*. Its growth seemed to be favored by the presence of 1.5 per cent of salt in the medium. The organism was important in the decay of fish muscle.

22. Shewan. 1938. Gt. Brit. Food Invest. Bd. Ann. Rpt. for 1937, p. 75; also Rpt. for 1938, 79-87.

It has been shown that unopened fish keep better than the opened owing to the fact that evisceration exposes the tissues to attack of bacteria. The intestinal canals of fish are apparently well seeded with many types of bacteria, both aerobic and anaerobic. When the fish is opened these may be released to infect and spoil the meat. Pernansky found both aerobes and anaerobes, many of which exhibited proteolytic tendencies. Wall²³ reported that freshly caught unopened herring kept better than the opened. Anderson²⁴ reported that the fish with greater amounts of food in the stomach decomposed more rapidly. Such spoilage is discussed again later under "feedy salmon."

Fish may, at times, harbor pathogenic bacteria. Johnson²⁵ has shown that fish may spread *Escherichia coli* and that this organism can multiply in the intestinal contents of fish. It is not difficult to understand how fish might be incriminated in the spread of certain diseases. If the water in which the fish lives, is polluted, objectionable bacteria will certainly get into the intestinal tract. During cleaning, the muscle may be contaminated. Harrison and his colleagues showed that cooking could not be depended upon to sterilize the tissue. Uhlrich¹¹ attributed a case of paratyphoid fever (type B) to fish. The medical officer of health reported that fish was a common cause of typhoid fever in London. The fish especially involved were plaice which were fried and had been sold ungutted on account of their small size. Cooking cannot be relied upon to destroy objectionable bacteria.

The intestinal contents of fish carry a varied microbiological flora probably determined largely by the food and water from which the fish is taken. Reed and Spence²⁶ found largely members of the genera *Achromobacter*, *Pseudomonas*, *Flavobacterium*, *Bacillus*, and members of the Coliform group. Members of the genus *Achromobacter* were also found in slime and intestinal contents of haddock by Stewart.²⁷ Micrococci were frequently found in slime but not in intestinal contents. Not many *Pseudomonas* types were found. Sporeforming bacteria were never found in the slime but were abundant in the intestinal contents. Gibbons²⁸ reported about the same general variety of microorganisms in the same materials. Special efforts were made by Lucke and Schwartz²⁹ to relate the bacterial flora of fish to the water from which they came. Fish taken from water with a high bacterial content did not keep well and had an undesirable flavor. The main infection seemed to occur during catching and handling when the fish might be damaged. The surface slime might be disturbed and the intestinal contents voided. Bacteria in sea-water ice and ships' holds are always a source of bacteria in fish. Insufficient refrigeration permit bacteria to develop in large numbers. Many changes were said to be necessary, both on ship and on shore, before some of these difficulties

can be eliminated. Further results of investigations quite like those just reported were published by Thjotta and Somme,³⁰ Snow and Beard,³¹ and Levinskaia.³² Most of the bacteriological work on fresh fish has concerned aerobic bacteria. Anaerobic bacteria are probably as important and perhaps more so in view of their marked ability to bring about decomposition. Shewan²² did not find anaerobic bacteria in slime but always in the intestinal contents. Those which were identified belonged to the genus *Clostridium* but were not much related to spoilage.

Spoilage of fresh fish is apparently not caused by members of any one genus. Wood³³ allowed fish to decompose at room temperature and at 40°C.(104°F.) and observed a large number of different bacteria. They came from the slime. Wood believed that the bacteria in the intestinal tract were unimportant in spoilage. His experiments pointed out what so many investigators have found, i.e., that proper handling and clean apparatus will do much to prevent undue spoilage. The bacteria isolated were species commonly found in soil, fresh water, and sea water, the principal genera being *Achromobacter*, *Micrococcus*, *Flavobacterium*, *Pseudomonas*, *Bacillus*, *Sarcina*, and *Serratia* in the order named. No special flora was present in the intestines, the gut of non-feeding fish being virtually sterile.

Many who have studied these problems have tried to determine the origin of spoilage bacteria and the types which are most prevalent. Bedford³⁴ reported the number of bacteria in surface water of the sea to be low but to vary within the same locality at different times of year. The lower depths of the sea had fewer bacteria than the surface. Bedford found that fish caught in the vicinity of fresh water are liable to contain more bacteria than those from salt water. However the number of bacteria on the surface of the fish was low and the number in the alimentary tract was not excessive. Some animal intestinal bacteria have been found in the alimentary canal of haddock but not on the surface of the fish. Growth of bacteria may be retarded by properly washing and eviscerating the fish, but under practical fishing and storage growth is rapid. The fishing vessel is a serious source of contamination. Griffiths and Stanby³⁵ tested eviscerated haddock kept over a period of 21 days and sampled at regular intervals to determine the changes that occurred. Bacterial changes were not suggested as a means of grading fish.

The nature of fish tissue make it susceptible to spoilage. Few foods must be handled more carefully and promptly. Lumley³⁶ blamed careless handling by trawler crews for spoilage by bacteria. Strict cleanliness and storage in ice is stressed. This advice was in accord with the results of extensive consideration of this problem by Lumley, Paqué, and Reay.³⁷

The bacterial content of decomposed fish would always be high even with slight decomposition. Schönberg³⁸ found that the most significant bacteria were gram-negative, slender, very motile rods which liquefied gelatin and grew best at room temperature. Gram-negative micrococci, *Proteus* species, coliform bacteria, and aerobic sporeformers were next in importance.

Tarr's³⁹ Direct Method for Counting Bacteria in Fish Flesh. The sample of fish is finely minced under conditions which do not permit the access of foreign bacteria. Some of the flesh, selected at random, is added to three times its weight of sterilized distilled water, the weight of fish added being determined indirectly by measuring the volume of water it displaces. Resulting mixture is transferred to a strong glass test tube containing some fine sand. Contents of the tube are stirred very rapidly for about a minute by means of a bent glass stirring rod rotated by a small electric motor. After standing for several minutes in order to permit the sand and coarser flesh particles to settle, the upper layer of rather cloudy liquid can be used for making the direct count and, if desired for purposes of comparison, the viable count as well. Actual count is carried out on a small accurately measured drop (.01 milliliter or about .0006 cubic inch) of liquid, which is placed on clean glass slide and spread over a marked-off definite area of one square centimeter (.155 square inch) with a fine needle. The resulting thin film of liquid is dried in air at about blood temperature. Slide is then placed for one minute in strong (90-95 per cent) grain alcohol, drained, transferred to a solution of blue dye (Loeffler's alkaline methylene blue) for about 30 seconds, rinsed very gently with tap water, and the film then dried in warm air. The bacteria are dyed a very dark blue while the background (consisting chiefly of fish muscle protein) is only a very pale blue. The bacteria seen in a selection of separate regions ("microscope fields") on this film as viewed under the microscope are counted and from the result it is possible to calculate the number of bacteria in given weight of fish. Result is expressed as the total number of bacteria per gram. Each microscope field represents only a minute fraction (about one seventy-millionth of an ounce) of original fish muscle. Thus if there were exactly 70,000,000 bacteria per ounce of the original muscle and these were absolutely evenly distributed, there would be only one bacterium per field. Experiments have indicated that this method cannot be used directly when there are less than about 3,000,000 bacteria per ounce of fish flesh. Greater numbers are counted with greater degrees of accuracy. The disintegrating apparatus used by Tarr was patterned after that of Haines.⁴⁰

***Escherichia coli* in Commercial Fish.** The position of coliform bacteria in sanitation has prompted investigators to determine whether members of this group have the same significance in fish that they have in other foods. Griffiths and Fellers⁴¹ observed that much of the fresh and frozen fish is sold as fillets or in other ready-to-cook form. This involved much handling. Bacteriological examinations by these investigators revealed that such handling contributed typical *Escherichia coli* to the product. Since these are of fecal origin, it was believed that their presence indicated undesirable conditions in preparation for the market. Fecal *Escherichia coli*, according to Gibbons,⁴² are not normal inhabitants of the alimentary tracts of fish except those which are caught near shore. They were said to be seldom present in fish caught at good distances from shore. Perhaps the organism may have the same significance which Hunter⁴³ suggests it

should have in cooked crab meat—that it indicates undesirable conditions of handling. The difficulty of keeping contamination out of a plant where fish are dressed and packed was indicated by Fitzgerald and Conway.¹ *Escherichia coli* was found on backs and gills by these investigators, even after washing them in hypochlorite solutions of strengths up to 100 parts per million. They were inclined to minimize the significance of *Escherichia coli* in fish fillets.

CODFISH

This fish is caught in great numbers off the Grand Banks of Newfoundland. Harrison, Perry, and Smith⁷ stated that Cabot in 1498 gave the mainland of North America the Basque name for codfish—"Bacalaos." French, Spaniards, and Portuguese frequented the Grand Banks before 1502, returning to their home ports with great numbers of cod. This was the beginning of an industry now amounting to millions of dollars concerned with the preparation of the fish in different forms.

Preparation of cod, which has been described by Bitting,⁴⁴ furnishes good illustration of use of salt for preserving flesh. He reported that 25,000 long tons of salt were used in a year at Gloucester, Mass., alone. As soon as the fish are caught, they are cleaned which consists in removing the head, viscera, and backbone. They are then piled up in the hold and sprinkled with salt. About 1.5 bushels of salt may be used per 100 pounds of fish. Water is drawn from the fish and the brine runs to the bottom of the hold from which it is pumped. Fishermen often attempt to reduce the amount of water taken from fish by using lesser amounts of salt so that the fish will weigh more in port. Souring often results. After the fish are on shore they may be further dried by means of salt. Fresh fish were said to require eight bushels of salt to the hogshead. Bitting stated that fine and coarse salt had about the same ability to extract water from fish over a long period. During the first two days, however, the fine salt accomplished greater dehydration. If the tissue comes in contact with large amounts of fine salt, it becomes "salt burned." The tissue is coagulated while the interior remains soft. The quality of salt was reported by Tressler⁴⁵ to have some importance as it has been found to be important in other fields. Calcium and magnesium sulfates are said to retard the penetration of salt. The dry-salt method was found to be superior to the brine-salting method. Very great is the importance of starting with a perfectly fresh fish for salting. Delay in salting allows microorganisms to start to develop and this put a heavier load on salt as a preserving agent.

Reddening of Codfish. Many explanations have been offered for the cause of this defect of salted fish and other foods. Farlow⁴⁶ seems to have been one of the first to study the question. He believed that reddening was due to a pigmented, slime-producing organism to which the name *Clathrocystis roseo-persicina* was given. Farlow found the organism about the packing plants and in the salt. Salt was believed to be the source of

the organism on the fish. Later he reported *Sarcina morrhuae* and *Oidium pulvunatum*. Since Farlow's contributions, many others have studied the problem and reported other fungi. Megnin⁴⁷ attributed the red color to a fungus, *Coniothecium bertherandi*. Roumeguere⁴⁸ believed the trouble was due to *Clathrocystis*. Poulsen⁴⁹ isolated an organism which was believed to be *Sarcina morrhuae*. Layet⁵⁰ and Edington found coccus forms to which they attributed the trouble. LeDantec⁵¹ distinguished two degrees of redness, apparently caused by different organisms. A sporeforming rod was believed to be of special importance. Results of researches by LeDantec⁵² attributed it to another organism. This organism was apparently a nonsporeformer and had the ability to grow in strong salt solutions. LeDantec showed that it came from the salt used for salting codfish. He proposed the term "chlorophile" for those organisms which needed salt for growth. Höye⁵³ believed that there was more than one organism which could form the red pigment; probably a *Sarcina* and *Micrococcus* were involved. He also mentioned a red micrococcus described by Johan-Olsen, *Sarcina rosaceae*. Höye believed that the methods of salting might be responsible for the development of the red color. Red bacteria were isolated from specimens of salt. Beckwith⁵⁴ isolated a *Diplococcus gadidarum* from reddened fish. The characteristic red color was produced on tubes of shredded codfish. According to Bitting,⁴⁴ the organisms which produce this spoilage probably live in sea water, and being salt-tolerant, are able to propagate on the fish. Pierce⁵⁵ suggested that the salt be sterilized. Absence of the trouble on the Pacific Coast was attributed by Cobb⁵⁶ to the fact that better salt was used. A Spirochaete and a bacillus producing a red color were believed to be the cause of the trouble by Browne.⁵⁷ Harrison and Kennedy,⁵⁸ Cloake,⁵⁹ and others have contributed to the subject, but added little that was new. Practically all of the various bacteria are pleomorphic and salt-tolerant. Harrison and Kennedy's organism grew well in the presence of 15 per cent of salt. The organisms are nonpathogenic as far as can be determined from the contributions which have been made to the subject.

Petrova⁶⁰ attributed reddening to *Micrococcus roseus*. The various bacteria which had been isolated and named by others were believed to be one species. *Serratia salinaria* was the name used by Kurochkin.⁶¹ Salt was believed to be the source. A halophilic bacterium requiring as much

as 20 per cent of salt, named *Vibrio halobicus desulfuricans* was isolated from salt and canned anchovies by Sontag.⁶²

Many of the investigators whose work has been reviewed above have found the organisms in salt. Stuart, Frey, and James⁶³ and Gibbons⁶⁴ confirmed this, the former finding them to be quite common in salt from many places in the world. The species isolated were placed among the higher bacteria. Two organisms were isolated from reddened cod and from salt by Shewan.⁶⁵ One was a bacillus and the other a micrococcus. Halophilic bacteria varied greatly in number in various salts—from 0 to 90,000 per gram of undried salt. Shewan believed that bacteria causing this defect could be classed in two main groups, *Serratia* and *Micrococci*. At this stage the fish deteriorate rapidly and smell bad.

Another discoloration of dried salt fish caused by a microorganism is "dim" salt fish. It is caused by a halophilic microorganism, *Torula epizoa* (*Sporendonema epizoum*), spores of which cause the chocolate-brown spots. Hess⁶⁶ found that fish could be contaminated by direct contact with infected fish or by utensils or by salt. Storage of fish below 5°C.(41°F.) prevented growth of the fungus. The fungus does not spoil the fish and may be brushed off. This situation is then comparable to that which obtains with cold-storage beef. Frank and Hess⁶⁷ found the organism to be halophilic, requiring a minimum of five per cent of salt, the optimum being between 10 and 15 per cent. Optimal humidity for growth was around 75 per cent. Ultraviolet light had little lethal effect on the organism.

Microbiology of Canned Cod-Fish Cake. Hanzawa and Takeda⁶⁸ reported isolation of a strict anaerobic, spore-forming bacterium and two nonsporeformers (*Serratia marcescens* and *Micrococcus acidilactici*) from a can of swelled codfish cake. The strict anaerobe, believed to be the cause of the spoilage, was a gas former of low heat resistance. It was killed in 60 minutes at 100°C.(212°F.) but not in 30 minutes. Heating under pressure killed it quickly. Although the product may have been understerilized or the cans may not have been sound, such bacteria have been reported in several meat products.

Microbiology of Fresh Salmon. Various interesting problems have been revealed in investigations of this subject. The general flora is influenced by the type of water from which the fish are taken, the methods of handling, and the state of feeding. Hunter¹³ found the muscular tissue of freshly caught salmon to be sterile. After 96 hours between 10°C.(50°F.), and 21.1°C.(70°F.), the count increased to as high as 155,000,000 per gram. In a later paper Hunter (1920) reported results of a study to determine what organisms are significant in decomposing salmon. Twenty-one out of 43 cultures were found to be members of the coliform group. In general, Hunter found that the organisms were really water, sewage,

and soil organisms. It would probably be a difficult matter as Bartlett has pointed out, for the industry to eliminate these organisms in the packing of the fish. Hunter⁶⁹ extended his study to samples of decomposing salmon and to sea water in the Alaska region. Members of the coliform group were common. *Aerobacter cloacae* and *Pseudomonas fluorescens* and an unidentified flesh-colored organism were important in decomposition of salmon. Eighty percent of bacteria collected from sea water were also found in decomposing salmon, in the canneries, or in both. Hunter stated that these data confirm the former conclusions that the decomposition of salmon is not due to bacteria acquired in the cannery. Fellers,⁷⁰ when in charge of the Pacific Fisheries Investigations for the National Canners Association, also found that the larger number of bacteria in spoiled salmon belonged to the coliform group of bacteria. *Aerobacter cloacae*-like organisms were also common and responsible for considerable spoilage of fish. The anaerobic, sporeforming bacteria were not commonly present in fish. Fellers also studied the penetration of bacteria into the tissue. The greatest contamination came from the gills and through the skin and not from the belly cavity. Salmon, on their way to the spawning grounds, were found to harbor few bacteria in the body cavity. Those that were found were in the stomach and intestines were of the usual water flora.

Fellers' investigations showed that salmon might become heavily contaminated at any of the following places: (a) scows and boats used in transporting salmon; (b) pewing of the fish through the body; (c) on the fish floor where blood, slime, and dead fish may infect good fish; (d) in sliming tanks where, due to insufficient changing, the water becomes badly polluted; (e) cutting machines and fillers; (f) dirty and dusty cans; (g) the water used in canning.

"Feedy" salmon have been found to decompose more rapidly than salmon whose intestinal tracts were empty. Desiring to find out whether decomposition of feedy salmon was entirely due to bacteria, Hunter⁶⁹ determined the number of bacteria in the stomach, intestines, and muscle tissues. No correlation was observed between the number of bacteria and the extent of decomposition but evidence was observed to indicate that agencies other than bacteria were concerned with decomposition. This work was extended by Hunter to hatchery salmon. Total counts of bacteria were made from the gills, flesh of the back, flesh of the belly, pyloric ceca, stomach, and intestines. The gill counts varied so greatly that little attention was given it. The highest count from the gills of a salmon which had been out of the water for six days was 3,600,000,000 per gram. The counts from the other organs were not significant since these organs are not eaten. However, they may contribute to foul odors. Hunter studied the anaerobes, but found none pathogenic for guinea pigs by mouth. In general, the organisms involved in spoilage were found to be the same in both the hatchery and migrating salmon. Fellers⁷¹ reported that bacteria

71. Fellers. 1926. *J. Bact.* 12, 181.

enter the flesh through the mouth, gills, anus, and skin, usually with slime, which is an excellent bacterial medium. The organisms found in decomposing salmon were those of river and sea water and did not constitute a separate group. Salmon flesh remains sterile for 20 to 60 hours after death, depending on such variables as temperature, size of fish, method of handling, and conditions of storage. Of 412 purified cultures obtained from decomposing salmon, 31 per cent were cocci, 4.5 per cent sporulating aerobes, 17.5 per cent aerobic, asporogenous, chromogenic bacilli, 36.5 per cent aerobic asporogenous, achromogenic bacilli, 6.8 per cent yeasts, 2 per cent obligate anaerobes, and 1.7 per cent spirilla. *Escherichia coli* is not a normal inhabitant of the intestines of the salmon. Slime is the greatest single factor in the spread of microorganisms of fish, boats, gear, and canneries. The canning process of 115.6°C.(240°F.) for 90 minutes in one-pound cans renders most of the cans commercially sterile.

Microbiology of Canned Salmon. Much has been written on this subject and probably a good portion of it no longer is applicable to the product as it exists today on the American market. Whereas at one time appreciable insterility existed in canned salmon, the situation is quite the reverse today. This is largely due to refinements in handling the fish after catching and to better methods in the packing plant as well as to better technic in examining the cans in the laboratory. Inspection procedures outlined by Clough and Clark⁷² have also had a large part in improving quality. The early literature probably does not reflect the condition of canned salmon today. In the tuna-packing industry, which probably does not differ basically from the salmon-packing industry, Lang⁷³ reported a general mixed flora in the product up to sterilization. Aerobic rods and cocci were most numerous. Sporeforming organisms were not isolated from unprocessed cans although they were observed at various stages. *Clostridium botulinum* was isolated directly from cuts prior to canning and therefore probably enters the can. Sporeforming bacteria must be uncommon, however, in tuna. Lang was inclined to consider them of importance even in small numbers. He also emphasized that dormant spores might be present in canned tuna.

Those who wish to know the situation which once existed in this industry should consult publications of Bushnell and Utt,⁷⁴ Sadler,⁷⁵ DeBord,⁷⁶ Savage, Hunwicke, and Calder,⁷⁷ Weinzirl,⁷⁸ and Fellers.⁷⁹

Since the investigations, results of which have just been discussed, were carried out, marked improvement has taken place in the quality of canned salmon. This is due not only to a general improvement throughout the entire food industry in sanitation and knowledge but also in the salmon

industry to introduction of new procedures. Williams and Clark⁸⁰ mentioned the use of mechanical vacuum in place of the steam exhaust as an example. They also mentioned the significantly severe processes of 90 minutes at 116.6°C. (242°F.) which are used to soften the bones and make them edible. This is in excess of the cook necessary to protect against spoilage. In spite of the fact that no reports of spoilage owing to under-sterilization have been made, Williams and Clark made a bacteriological survey of canned salmon with adequate controls to determine the actual bacteriological condition of the product. They found the cans which they examined to be bacteriologically sterile, indicating that packing procedures and processes now in use are adequate. In this paper Williams and Clark discuss the problem of air-borne contaminations on plates made in similar surveys, a subject discussed in this book in Chapter 23. How much contamination may have occurred in former investigations can never be known.

Mild Curing of Salmon. The fish are split down the middle and the backbone cut out. Each half of the fish secured in this manner is then scored eight or nine times with a knife. After being soaked in cold water for an hour or so, the fish is salted in tiers. Little salt is used and consequently the fish must be kept in cold storage until used. This mild-cured salmon is used for smoking. It is quickly freshened by soaking in water and a practically fresh fish is then available for other treatment.

Pickling Salmon. The fish is split and the viscera removed. After washing, it is put into pickling butts with about 15 pounds of salt for each 100 pounds of fish. After a week they are packed into barrels with salt for the market. Dry salting may also be used, in which process the fish are packed into boxes with salt. Smoking is often done after the fish are preserved in a pickle until they can be smoked. They are taken from the pickle and washed free of as much salt as possible. Then they are subjected to smoldering fires for three or four days. Other varieties of fish may be preserved in the same manner.

Growth of and Toxin Formation of *Clostridium botulinum* in Canned Salmon. *Clostridium botulinum* is able to grow and form toxin in canned salmon. Schoenholz, Esty, and Meyer⁸¹ inoculated cans of salmon with toxin-free spores and after incubation for varying lengths of time secured spoilage. The partially liquefied contents gave off a putrid odor. Six of eight cans of salmon inoculated by Thompson and Tanner⁸² spoiled and became toxic. *Clostridium botulinum* is apparently in the cannery, for Lang⁷³ observed Type A strains in slime and cleaned flesh of salmon before canning. About one per cent of empty cans were also found to harbor this organism.

PRESERVATION OF FISH

Many different procedures are used for preservation of fish. Some of them completely change the appearance and flavor while others maintain the tissue close to the normal and natural condition. All of them repress

80. Williams and Clark. 1942. Food Research 7, 178-185.

81. Schoenholz, Esty, and Meyer. 1923. J. Infect. Dis. 33, 289-327.

82. Thompson and Tanner. 1925. Idem 37, 344-352.

bacterial development or destroy bacteria. Icing has been used to a large extent for holding fish until other methods could be used. Ice may carry many bacteria among which may be species which are definitely objectionable. Watson⁸³ found some ice being used in fish preservation to contain 25,000 bacteria per milliliter. The predominating organism was *Pseudomonas fluorescens* which caused discoloration of fish muscle. *Bacillus platychoma* and *Bacillus simplex*, which caused decomposition, were also isolated. Watson suggested use of paper to keep fish from coming in contact with the ice.

Various preservatives have been added to fish for many years. According to Tarr and Sunderland,⁸⁴ Norwegian experts as early as 1870 prevented deterioration of salted herring shipped to England by adding boric acid to the pickle. The same practice was used in other countries although at times other preservatives were introduced. Stringent food laws, however, have largely prohibited such preservatives although in some countries they are permitted if their presence is indicated on the label. Fish in the past have been immersed into such solutions as sodium hypochlorite, formaldehyde, boric acid, potassium nitrate, and even in strong salt solutions immediately after gutting and just prior to icing. More recently sterilizing ices containing various chemical compounds, such as hypochlorites, benzoic acid, and ozone, have been used. Still more recently the fish have been stored in atmospheres containing large amounts of carbon dioxide. All of these procedures, according to the above-mentioned authors have not been very successful. Experiments in their own laboratories with some ten more or less common preservatives indicated that potassium nitrite in quite low concentrations strongly inhibited the rate of spoilage in fillets. The Canadian Food and Drugs Act of 1938 permits the use of refined sodium nitrite in concentrations of .02 per cent for curing meats and fish. Hydrogen peroxide, hydrochloric acid, and boric acid in the concentrations which were employed were not very effective. Hydrochloric acid and sulfur dioxide resulted in a product with a rather unpleasant appearance. The latter also produced an unpleasant odor and flavor because it apparently acted with the oils in the fish. Chloroform was very active and had the advantage that it later evaporates rather quickly on storage of the fish. Sodium benzoate also showed some activity. Tarr and Sunderland reported that inhibition of bacterial growth varied with each particular preservative and especially with the species of fish. Results of organoleptic examination checked quite well with the results of bacteriological data reported. These authors also reported that the chemical preservatives used were in general more efficient in reducing the number of viable bacteria than was ultraviolet light. Later, Tarr and Sunderland reported that sodium nitrite was as efficient a preservative as was potassium nitrite.

Salt. Large quantities of salt fish are prepared in most countries in the world. The factors involved are probably about the same as those involved

83. Watson. 1934. *Canad. Fisherman* 21, 25-28.

84. Tarr and Sunderland. 1939. *Pacific Biol. Sta. and Pacific Fish. Expt. Sta. Prog. Rpts.* 39, 13-16; 40 (1939), 14-17.

in preservation of other foods by salt. A dry cure may be used or the fish may be placed in salt solutions. If the fish carries few bacteria, the load on the curing process is lighter. Bedford⁸⁵ observed that immersion of fresh halibut in 20 per cent salt solution for 30 minutes immediately after gutting preserved them well. Criteria were retardation of yellow discoloration of the white skin and the number of bacteria. According to Burova and Nasledysheva⁸⁶ pathogenic microorganisms are restrained by salt solutions used in curing fish.

Survival of Pathogenic Bacteria on Salted Fish. Whether salt fish would be significant in spreading any pathogenic bacteria which might be in sea water is questionable even though it is known that *Eberthella typhosa* may exist for some few days. Kenyoun⁸⁷ found that this organism could exist in high salt concentrations. Frank and Hess⁸⁸ recovered *Eberthella typhosa* from salt fish blocks after 22 days at 5 to 6°C. (41 to 42.8°F.) and from salt media after periods as long as 94 days. *Escherichia coli* was found under the same conditions after 72 days and on salt media after 91 days. *Escherichia coli* is considered a good indicator of pollution when the storage period is known. Its presence indicates previous contaminations and potential danger. Methods of preparation of the fish would probably be one element of safety.

Chlorine Compounds. These compounds are playing a great role in sanitizing food-processing plants. They are also used on the trawlers and in ice used to chill freshly caught fish. Moran and Piqué⁸⁹ secured good results when hypochlorites were put into the ice. Results of a comprehensive investigation were reported by Chen and Fellers.⁴ Immersion of eulachon before packing in a solution containing .6 per cent of available chlorine for five minutes materially reduced the bacterial content of the fish and enhanced keeping quality. Solutions with less than .2 per cent were not effective. They also reported the beneficial effects of using hypochlorite containing ice. Disinfection with chlorine was also of value when fish was dried. *Torula epizoa* was inhibited (Notevarp and Larsen⁹⁰). Chlorine compounds seem to have been of value in handling of various foods from the sea.

Carbon Dioxide. This gas has been studied as a preservative for many different foods. The results have been quite variable owing to the fact that microorganisms vary in their response to the gas, some being inhibited while others are benefited. Such was the experience of Coyne.⁹¹ Working with various species of *Achromobacter* that are associated with fresh fish, he observed that moderate or large amounts of carbon dioxide inhibited growth. This was especially marked at 0 to 10°C. (32 to 50°F.) at which temperatures these bacteria could ordinarily grow. In an atmosphere con-

taining 20 per cent of carbon dioxide, and at a temperature of 0°C. (32°F.) the bacteria were almost completely inhibited. Marked preservative properties of the gas for haddock were also reported by Stansby and Griffith⁹² who also commented on improved quality. Coyne believed that the preservative action might be due to an intracellular change in pH owing to permeability of the living cell to carbon dioxide and even to interference with some essential enzyme system.

Nitrites. Sodium nitrite has been shown to exert a preservative action in meat curing. Tarr and Sunderland⁹³ studied it as a preservative of fish. Dressed halibut, pink salmon, and black cod spoiled less rapidly when dipped into water containing .05 to .2 per cent of sodium nitrite than when packed in ordinary water ice or benzoic acid ice. Its preservative ability was believed to depend on its ability to penetrate the fish tissue. Tarr later reported further confirmation of these observations.

Ultraviolet Light. In view of prohibition of chemical preservatives in fish and fish products Tarr and his colleagues, Young and Sunderland,⁹⁴ attempted to use ultraviolet light for keeping fresh fish fillets. They were inclined to interpret their results favorably, for the exposed fish had fewer bacteria and better flavor and odor than the unexposed. The action was admitted to be limited to the surface with no penetration. Five to 10 minutes' exposure was necessary under conditions in their experiments.

Benzoated Brine Dips and Benzoated Ice. Results of an investigation by Fellers and Harvey⁹⁵ showed that it was entirely practical to freeze as much as .5 per cent of sodium benzoate in ice. Since its distribution in the ice cake was uneven, they recommended use of this ice in the crushed form. Fish stored in such ice kept several more days than did fish stored in ordinary ice. The benzoates were more effective when acidulated. Good results were also secured by dipping fillets for two minutes into brine containing sodium benzoates. Only slight improvement in keeping quality of dressed halibut and black cod was observed by Tarr and Bailey⁹⁶ when the fish were stored in crushed ice containing .1 per cent benzoic acid instead of plain ice. Viable bacterial population and trimethylamine content of the muscle were used as criteria.

Smoked Fish. Smoke is used for curing fish just as it is used for some meats. Hess,⁹⁷ in seeking information of the bacteriological aspects of the industry, used artificial media on account of the difficulties of sterilizing fish flesh without changing its character entirely and to obtain a uniform culture material. Three strains of bacteria (a staphylococcus, a nonspore-forming rod [*Proteus vulgaris*] and a sporeformer of the *Subtilis-mesentericus* group) were used in several experiments to determine bacterial action of smoke under various conditions. The arbitrary scale: "Cubic

foot of air admitted to the smoke producer per hour'' gave a fair indication of the smoke concentration. An increase of the amount of air admitted per hour caused uniformly a greater reduction of bacteria, *i.e.*, an increase of the bactericidal power of the smoke, as well as visibly, a higher density or opaqueness of the smoke. Smoke from different sources (sawdust from hardwood, softwood, and mixtures of both) showed practically no difference in bactericidal power after six hours' action upon the test organisms. The rate of reduction of nonsporeformers under experimental conditions was greatest between one-half to two hours of exposure to fairly weak smoke, with an initial weakening of the bacteria during the first half hour and the killing of the more resistant forms during the third hour of exposure. The more concentrated the smoke, the greater was the initial and the total rates of reduction. Bacterial spores were found to be very resistant to smoke, the resistance increasing with increasing age of the spore cultures; 71 per cent of the spores from a seven-months-old spore culture survived exposure to a dense smoke for seven hours, while non-sporing organisms were killed in one to two hours by the same smoke. Penetration of smoke was found to be fairly rapid through peptone-water, slow through a flour paste, and very irregular through slices of fish muscle. The more concentrated the smoke the higher its penetrating power. Smoke constituents which had been absorbed by the smoked media during the exposure, continued to exert a bactericidal action upon the test organisms after the smoking process was finished. Formaldehyde vapors, containing three or more grams of formaldehyde per 100 cubic feet, approximately in the same concentration as they occur in ordinary smoke, have a decided bactericidal action. Formaldehyde is considered one of the chief bactericidal constituents of smoke. The resistance of bacteria against smoke is greatest in media of optimum salt concentration. The influence of the presence of proteins upon the bactericidal action of smoke was determined, using peptone solutions and fish extracts. Both were shown to have a decreasing "quenching" action upon the effect of smoking; this was less conspicuous in case of dense smoke than when less dense smoke was used. The hydrogen-ion concentration of unbuffered media is greatly increased during smoking. The bactericidal action of smoke in buffered media was shown to be greatest in an acid medium and decreasing constantly towards the alkaline side of neutrality. Callow⁹⁸ found formaldehyde on various smoked meats, its origin being wood smoke. It has been found in smoked fish as well. Callow stated that the presence of formaldehyde in wood smoke does not prohibit the use of smoke as a preservative in England.

Smoked Haddock and "Finnan Haddies." This type of smoked fish probably had its origin in Findon on the north coast of Scotland. It is now prepared to some extent in the United States and Canada (Patterson⁹⁹). Under some conditions, flavor must be sacrificed for preservation. Fresh haddock are beheaded, split, and eviscerated; an extra cut is also made in the back in order to facilitate curing of the thick back muscles.

98. Callow. 1927. *The Analyst* 52, 391.

99. Patterson. 1917-1918. *Bull. Biol. Sta. Canada*.

The fish is then salted in strong brine for 30 minutes. They are then smoked for five to six hours in dense peat or sawdust smoke. The Canadian method, as outlined by Patterson, is a little different. It was found that small fish need not be salted more than 15 minutes. Thirty minutes' salting seemed to be the proper period for the average sized fish—this to be followed by 10 hours' smoking. A longer smoking increased the preservation but detracted from the flavor. Harrison¹⁰⁰ examined the intestinal contents of 12 haddock and reported *Bacillus vulgaris* Hauser to predominate. It was also found on and in the flesh of smoked haddock and haddock which had spoiled. The salting and smoking were found to be insufficient to destroy the organism. This makes it imperative that the fish be carefully handled and the process of treatment started as soon after removal of the fish from the water as possible.

After immersion in strong brine for 20 to 30 minutes, according to Hess,¹⁰¹ they are removed and placed on iron rods to drain. On these rods, they are hung in the smokehouse where they are, first of all, dried by clear hardwood fires with the smokehouse well ventilated. After drying, the fires are partly smothered with sawdust to produce a dense smoke which is maintained until the desired cure is attained. The total time from the beginning of the cure to the end of smoking is from seven to nine hours. The same process for smoking finnan haddies would require from 13 to 17 hours. If the smoked fillets are to be held for any length of time they are frozen. Hess discussed the preserving value of several of the steps in smoking of fish. Since his discussion is of interest in preservation of different varieties of meat, some of it is presented. The initial pickling in heavy brine causes a decrease in volume but not in weight. The brine draws the water from the tissue but the weight is maintained by salt going into the muscle. Hess stated that this treatment also improved the surface of the meat. The drying just before smoking caused the formation of a pellicle over the surface of the fish. During drying there is sufficient heat to cause slight coagulation of the protein.

FREEZING OF FISH

This method of preservation has the advantage that fish is kept fresh. It is possible to ship frozen fish to inland places and have it fresh and sound. The early history of the industry has been reviewed by Taylor¹⁰² and Stiles.¹⁰³ Cobb¹⁰⁴ stated that salmon were frozen as early as 1894. When frozen fish were first marketed they encountered some opposition because the quality was not high. Introduction of efficient freezers and methods for keeping them frozen soon dispelled early prejudice. The frozen fish industry is a large one today.

One of the difficulties in preservation of foods by freezing is loss of considerable water when they are thawed which means loss of flavor and nutrient substances. Investigations revealed that this was not as true

100. Harrison. 1917-1918. Contrib. Canad. Biol. and Fish.

with quick-frozen as with slow-frozen fish. In the former, the ice crystals are smaller and were believed to cause less rupture of tissue cells, which results in loss of moisture on thawing. While this theory is reasonable it may not explain all of the facts.

Various investigators have shown that the rate of death of bacteria in fresh frozen fish is quite high in the beginning, declines later, and becomes quite constant. Hes¹⁰⁵ followed growth and pigment formation of *Pseudomonas fluorescens* and *Flavobacterium deceduosum* on nutrient agar at zero and just below. They remained active at these temperatures for five weeks. Adaptation to low temperatures was observed. Gibbons¹⁰⁶ made similar observations. Kiser and Beckwith¹⁰⁷ observed a higher death rate of bacteria when frozen. A reduction of 40 to 70 per cent of viable cells was observed when marine bacteria were frozen for eight minutes at $-16^{\circ}\text{C}.$ ($3.2^{\circ}\text{F}.$) in sea water and 99.9 per cent after 4.5 hours. Freezing at a storage temperature of $-28^{\circ}\text{C}.$ ($-18.4^{\circ}\text{F}.$) for 10 days caused sharp reduction in the bacterial flora of muscle and intestinal contents of mackerel.

Freezing of Fish in Air. Coolers are used for this purpose, the temperatures of which are kept low enough to freeze the fish. The temperature employed is determined by various factors. It is known that rapid freezing is desired, but the expense involved causes the selection of temperatures as high as are consistent with commercial results.

Freezing in Solutions. According to Taylor,¹⁰⁸ use of brine for freezing fish is not a new idea. Temperatures as low as $-12.2^{\circ}\text{C}.$ ($10.4^{\circ}\text{F}.$) may be secured with 22.4 per cent of salt and 77.6 percent of water. Taylor stated that the method, introduced a long time ago, was allowed to die out, only to be reviewed again in more recent times.

The fish are put into brine at a temperature below the freezing point of the fish. In brine at a temperature of $-17.8^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$) fish freeze in from 30 minutes to four hours. Taylor stated that there is some evidence to show that brine-frozen fish are firmer after defrosting than fish which have been frozen in the air. Fish which are frozen in air are said to have large ice crystals in the tissue which cause a breakdown in structure, leaving the fish soft. Experiments were conducted in shipping brine-frozen fish for great distances (2,200 miles in four days) without ice or insulation. They were reported to have arrived in excellent condition. In another case, brine-frozen fish were shipped 1,000 miles by parcel post in a corrugated paper carton without icing. They arrived in fine condition. It seems that brine-frozen fish can be refrozen after being defrosted. It is probable that cold brine has distinct bactericidal action. The advantages of this method of preserving fish for distribution should make it a very useful method in the future. Stiles¹⁰³ has reported results of investigations on the freezing of fish in brine. Choice of a cooling solution is limited to one which will not harm the consumer or the tissues of the fish. This practically drives the industry to common salt. Stiles quoted the work Middendorp,

105. Hes. 1934. *Canad. Biol. and Fish.* 8, 461-472.

who observed that intake of salt varied with time, but that the intake was not the same in various parts of the fish. The wall of the body cavity seems to have the greatest affinity for salt. Almy and Field¹⁰⁹ studied penetration of salt into skin and superficial layers of tissues of weakfish, flounders, and whiting during immersion for different periods of time in cold brines of different temperatures and concentration. Under all conditions salt was found to penetrate under the skin and superficial muscular tissues, but in amounts too small to affect the taste of the cooked fish. The results for salt penetration with varying temperature and concentration of brine were found to be insignificant and inconsistent; fish which had been precooled to about 0°C. (32°F.), before placing in the brine absorbed only 35 to 65 per cent of the salt absorbed when immersed at ordinary temperature. The amount and rate of penetration of salt into tissues varied with the species. With weakfish and flounders, most of the salt was absorbed during the first 30 minutes, while with whiting and herring absorption was more gradual. This was thought to be due to inequalities of fat content of the subcutaneous and body tissues of the fish. Fish frozen in 15 per cent brine were found to gain slightly in weight while those frozen in air at -10°C. (14°F.) lost weight. Subsequent storage of frozen fish in air caused a greater loss. It was found possible to obtain a satisfactory glaze in brine-frozen fish by rinsing in cold water and holding in storage for 12 hours. From the standpoint of bacterial decomposition, there was little choice between the two methods. The subject has been discussed by Birdseye,¹¹⁰ in reports on results of quick-freezing of animal tissue. Quick-frozen flesh passes through the zone of maximum crystal formation so that the resulting ice crystals are very small and do not rupture or compress the tissue. Birdseye compared "slow-frozen" and "quick-frozen" haddock under the microscope, finding much to favor the quick-frozen product. Birdseye's explanation for the superiority of quick-freezing was doubted by Taylor.¹¹¹

According to Clark¹¹² and his colleagues, freezing of fish suffices to hold them in their original condition but will not correct any faults owing to careless handling or heat. Only fish of high quality should be frozen. Glazing by surrounding the fish with a coating of ice has distinct advantages. The moisture remains constant and the meat is protected from the action of bacteria and molds. Fish to be stored for three to five months should be reglazed. From -18 to -13°C. (-4 to 8.6°F.) seem to be the best temperatures. Chemical analyses conducted by Clark could detect no significant changes in fish kept for 27 months or for a longer time than would ordinarily obtain under commercial conditions. Browne¹¹³ studied the bacterial life in fish stored in ice. The fresh fish muscle seemed to be sterile. Drawn fish showed the presence of more bacteria as the storage period lengthened. Undrawn fish stored for two to three weeks in dirty

ice showed few bacteria. Browne regards autolysis as a more important factor than bacteria in fish spoilage at low temperatures. While investigations of Clark and Almy,¹¹⁴ unfortunately, involved no microbiological examination, we may probably establish by inference some of the changes which took place. Both types of fish which were examined were in good condition for 16 and 13 months when glazed with ice. Very little difference was reported between eviscerated and uneviscerated fish when stored in the glazed condition. Unopened fresh herring, examined by Sven,¹¹⁵ kept well for three weeks to one month, but after this time became poorer and finally molded. Almy, Field, and Hill¹¹⁶ carried on investigations to determine the relative keeping quality of different kinds of fish in the eviscerated and uneviscerated condition in ice. Sea trout and mullet remained in marketable condition five days longer than Spanish mackerel. Gutting improved the keeping quality of mullet.

Psychrophilic bacteria were found to be commonly present in spoiled ice fillets by Sanborn.¹¹⁷ The fillets were about 10 months old and had been stored at $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$). They showed definite signs of spoilage with evidence of bacterial decomposition. The following bacteria were held responsible for the spoilage: *Proteus vulgaris* Hansen, *Chateostylum Fresenii*, *Eberthella bienstockii* Schröter, *Micrococcus subcitreus* Migula, and *Micrococcus candidus* Cohn. These organisms are, in the main, putrefactive in character and probably originate in the intestines of the fish. Sanborn believed that better methods of preparation would greatly improve keeping quality.

Very important among the factors influencing spoilage of fish is temperature of storage. Much work has been carried out on the influence of freezing and temperatures just above freezing on the bacterial flora. Nickerson and Proctor¹¹⁸ followed the changes in frozen fish indicated by chemical examination and tried to relate them to the bacterial flora. The haddock were frozen within an hour of being taken from the sea and kept at $-17.8^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$) or below until examined. The samples for examination were then incubated at temperatures ranging from 0 to $15^{\circ}\text{C}.$ (32 to $59^{\circ}\text{F}.$) and examined at various periods up to 120 hours. The sterile muscle samples showed a slight development of alkalinity measured as an increased pH; the amino acids showed an increase followed by a definite decrease. The ammonia nitrogen figure tended to show similar results when the fish was kept at 5 to $15^{\circ}\text{C}.$ (41 to $59^{\circ}\text{F}.$). With samples which were naturally bacterially contaminated the changes were rather more pronounced and showed a slight increase in pH, a more definite rise and fall of amino acids, and greater increases in ammonia nitrogen.

Freezing by Glazing with Ice. In order to prevent loss of water from frozen fish and consequent changes caused by dehydration, Bedford¹¹⁹ glazed frozen fish with a film of ice. This glaze is very brittle and cracks

easily when the fish are placed in storage. This is a satisfactory method and effectively controls bacterial development. Most of the published papers on the methods are concerned with methods of treating and storage. Proper packaging and storage of fresh fish products are quite necessary for maintenance of good quality. Birdseye's¹¹⁰ tests showed that packaging before freezing gives best results as regards thawing resistance, protection from deterioration, adaptability to quick-freezing manipulation, and wrapping cost. A method for testing the relative moisture-vapor-proofness of wrapping materials was devised. Comparative properties of many kinds of wrapping, packaging, and container materials are given.

Frozen fish, particularly oily fish such as salmon, become red sometimes on the cut surfaces, a condition known as "rusting." Bedford¹²⁰ believed that the cause was of bacterial origin but he did not isolate any cultures. The red pigment was believed to be a volatile substance from the bacteria which combined with the oil.

CANNED MARINE PRODUCTS

Preservation of certain marine products by canning is a large industry the world over. The problems involved are about the same as those for other canned foods, especially meats. Causes of spoilage, however, are different.

Nongaseous Spoilage. This has been found to be due to aerobic, spore-forming bacteria by Fellers.¹²¹ The group was represented by *Bacillus cereus* and *Bacillus mesentericus*. These bacteria show variable proteolytic properties. The principal changes in the canned fish product are softening of texture, marked turbidity of liquor, slight to marked abnormal odor and taste, and occasional slight discoloration. Fellers reported this type of spoilage to be more marked in cans having low vacuum or none, though the bacteria responsible may grow and produce fewer pronounced changes in cans having good vacuum of eight to ten inches of mercury. Fellers also stressed the fact that distinction must be made between active growth of bacteria in canned foods and mere presence of inactive spores. This situation is much better understood today than when Fellers made the statement. These organisms were also encountered by Lang⁷³ in underprocessed cans of salmon.

Gaseous Spoilage. This is evidenced by bulged ends of the cans. The microorganisms are usually anaerobic sporeformers among which are *Clostridium welchii* and *Clostridium sporogenes*. Jarvis stated that gas formation of these types is usually accompanied by an extremely foul and offensive odor. Another gas-forming, heat-resistant anaerobe is *Clostridium botulinum*. While this organism has been found in home-canned fish products, it has not been found in factory-canned products since 1925. Lang found no thermophilic, sporeforming gas formers in cans of fish which had been processed.

Thermophilic Spoilage. Jarvis stated that thermophilic spoilage might appear in canned-fish products which are held in warm warehouses. Stor-

120. Bedford. 1934. Cold Storage 37, 66.

121. Fellers. 1927. Univ. Wash., Pub. Fisheries 1, 229-238.

age at temperatures between 4.4°C.(40°F.) to 10°C.(50°F.) will reduce thermophilic spoilage.

Home Canning of Fish and Fish Products. The microbiological problems of home canning of fishery products are the same as those for canning meats in the home. These are discussed at some length in Chapter 23. Jarvis and Griffiths¹²² recommended the use of a pressure cooker for sterilization and that no tin container larger than No. 2, nor glass container larger than the wide-mouth pint jar be used. Pressure processes recommended by Jarvis and Griffiths are severe enough to yield a sterile product if strictly followed. They pointed out however, the mere use of a pressure cooker might not be enough. It must be used properly and process times counted only from the time the required temperature and pressure have been reached.

EXAMINATION OF CANNED FISH

The methods used are generally those used with other canned foods, *i.e.*, physical inspection of the containers and physical, chemical, and bacteriological examination of the contents. All of these examinations must be made by those who are competent in each field. Savage *et al.*,⁷⁷ Jarvis¹²³ and Clark, Clough, Fellers, and Shostrom¹²⁴ have prepared recommended procedures for examination of canned-fish products. All of them cannot be reproduced here.

Lang's¹²⁵ Procedure for Microbiological Examination of Canned-Fish Products. The suggested bacteriological methods concern chiefly the examination of so-called "non-acid," "low-salt" canned fishery products. Such products may be examined for sterility (keeping qualities) or for causes of spoilage owing to inadequate retort process or mechanical imperfections of the container. Sample cans that are submitted for sterility are in the main normal in appearance. Those cans submitted for determination of spoilage causes are usually abnormal to a degree that characterizes them as "flippers," "springers," "soft swells," or "hard swells." These cans may be further defective in that they have certain mechanical imperfections, such as dents owing to rough handling, faulty cover or side seams, or perforations.

PRELIMINARY INCUBATION

All normal cans submitted for sterility tests and examination for keeping quality should be incubated at 37.5°C.(99°F.) for a period of one month prior to cultural examination. Cans should be laid on their sides in the incubator to prevent drying of the can seams. It is well also to move the container slightly at intervals during the course of incubation. A record should be made of any changes occurring in the condition of the container during incubation.

Although an incubation period of one month is proposed here the time of incubation adopted and reported in the literature by other investigators has been found to vary. Weinzirl¹²⁶ used seven days or longer at 37.5°C.; Savage, Hunwicke, and Calder⁷⁷ used incubation periods of "several weeks," and Cheyney¹²⁷ records one to six weeks, with a two weeks' period as the general average. Cameron,¹²⁸ in his report on "Methods for the Examination of Canned Meats," states:

... unspoiled samples submitted for examination as to keeping quality should be incubated at 37.5°C. for a period of one month. This time of incubation, necessarily

an arbitrary matter, is considered the longest period that is practicable in the usual case. Anaerobes, which at times may remain dormant for many months, may escape detection, but usually the likelihood of spoilage in the product under ordinary commercial conditions of handling is indicated in this time. It is regarded as unnecessary to incubate at thermophilic temperature, *i.e.*, 55°C., because such spoilage in meat products is extremely rare.

The same conditions cited by Cameron prevail with respect to nonacid canned fishery products, as with meat products, it is unnecessary to test for thermophilic bacteria by incubating at 55°C. according to Lang.⁷³

A. Physical Examination and Preparation of the Can.

1. Make a complete set of records concerning the cans submitted (origin of samples, type of product, code marks, label, pertinent information concerning raw material and its pretreatment, and retort processes).

2. Make a record of the condition of the samples, noting mechanical defects, perforations, rust spots, dents, and all other can abnormalities. When spoilage is involved, ascertain the extent and determine whether one or several days' packs are affected.

3. Take all possible precautions to provide aseptic conditions when the cans are opened for cultural or enrichment examination. Have available a clean and disinfected table or desk top constructed of some type of impervious material. (If air-borne contamination is imminent, it is advisable to carry out the cultural or enrichment procedure in a previously disinfected room, or under a hood especially designed for this purpose.) Scrub the container with sand soap, using a brush and warm water. To remove grease, oil, or outside lacquer, wipe the can with some suitable solvent (a solution of equal parts of ethyl alcohol and ethyl ether is recommended).

4. Sterilize the surface of the can at the point to be opened by holding and slowly rotating the can inverted in the flame of a Bunsen burner. (Rotating will serve to secure an even area of sterilization and will prevent scorching the contents.) Heat flat or normal cans in this manner until one of the ends becomes distended, since internal pressure promotes an expelling action and helps to avoid contamination when the can is opened. When examining swollen cans do the flaming with caution, and if necessary reduce the internal pressure by refrigeration of the container prior to flaming. When flaming is not practicable, follow the procedure involving treatment with bichloride of mercury (1 + 100) described by Fellers,¹²⁹ or that suggested by Cameron,¹²⁸ calling for thorough cleansing with 60 per cent alcohol.

B. Removal of Sample.

1. Open the can at the point of sterilization with a suitable and previously sterilized opener. Have the opening as close to the center of the cover as possible and only large enough to permit adequate sampling. (A long handled can opener designed to cut in the circular direction in which the cutting edge travels as the circumference of a circle is best adapted for this purpose. This type of can opener lends itself quite readily to individual wrapping and sterilization, and also has the added advantage of preventing contact of the analyst's hands with the sterilized portion of the can.)

2. Determine the type of instrument to be used for removing the inoculum by the nature of the product under examination. (This operation is discussed by Tanner.¹³⁰) For consistently satisfactory results for canned fishery products use either large aperture pipets or sterile teaspoons, depending upon the product. Sample liquid or semiliquid products with large-bore, untapered, sterile pipets. Sample solid materials with teaspoons or other suitable instruments, such as cork borers or brass tubes that have been sterilized.¹³¹ (One advantage in using teaspoons is that a separate spoon may be used for each can, the spoons having been previously sterilized by being placed in a large metal receptacle and subjected to 15 pounds' pressure for 60 minutes.) Remove from the product a representative sample of 10 to 15 grams of material for inoculation into culture media. In making the inoculations carefully observe that the ratio of the volume

129. Fellers. 1936. *J. Assoc. Off. Agr. Chem.* 19, 430.

130. Tanner. 1936. *Idem* 19, 432.

131. *J. Assoc. Off. Agr. Chem.* 20 (1937), 431.

of the sample to that of the medium is not such as to affect the *pH* of the medium. If the can contents are fluid, tube and plate cultures may be made directly. If the material is solid, it may be inoculated directly into medium wide-mouthed flasks, which are cork stoppered and covered with vegetable parchment paper, or if plate cultures are desired, the solid material may be shaken in a sterile bottle with sterile broken glass and sterile saline solution until a proper suspension is secured for use as inoculum.

Place an additional sample in a sterile flask and hold in reserve under refrigeration for possible re-examination or for toxicity tests.

C. Culture Media

Prepare both anaerobic and aerobic cultures from the material secured as a sample. In preparing anaerobic cultures, use an unheated portion of the sample and a portion that has been heated for 30 minutes at 80°C.(176°F.) to destroy vegetative forms in order to test for the presence of anaerobic spores. Prepare an aerobic broth culture. (The preparation of plate cultures is optional and may be desirable under some circumstances.)

The culture media suggested by Cameron,¹³² are well adapted to the examination of fishery products. Those prepared from dehydrated media marketed by the Difco Laboratories, Inc., Detroit, Michigan, are especially suitable. Considerable success has been attained with the following media, which are also recommended:

Beef Heart Broth

Distilled water.....	1000 ml.
Minced fresh fat-free beef heart.....	500 grams
Difco Neopeptone.....	10 grams
C. P. NaCl.....	5 grams

With the exception of the NaCl, mix the ingredients in a steam kettle and boil for approximately 10 minutes. Remove the broth, filter, and adjust to *pH* 7.6 to 7.8. Boil gently for approximately 10 minutes, filter, and add the salt. Bottle or tube, preferably in hard glass containers, and sterilize for 20 minutes at 115°C.(239°F.). The range of the final *pH* should be from 7.0 to 7.4.

Beef Heart Agar

Add two per cent of agar to the above broth; or preferably mix the shredded agar with 500 ml. of the distilled water required, using the other 500 ml. for the preparation of the infusion. Then mix the two portions.

Heart Meat Broth for Anaerobic Enrichment

Place the residue of the ground beef hearts approximately 1 to 1.5 inches deep, into wide-mouthed flasks or tubes. Add the beef heart broth to bring the supernatant liquid 1 to 1.5 inches above the meat, stratify with vaseline, and sterilize in the autoclave at 10 pounds' steam pressure for 20 minutes.

(It is recommended that all culture media be incubated for 24 to 48 hours before use.)

D. Incubation and Culture Study.

Incubate all cultures for at least 48 hours at 37.5°C., and if practicable incubate anaerobic cultures at least 72 hours.

Use the Manual of Methods for Pure Culture Study of Bacteria of the Society of American Bacteriologists as a guide for the further study of microorganisms obtained in the cultural procedure described.

Clark, Clough, Fellers, and Shostrom's¹²⁴ Methods for Examination of Canned Salmon. While these procedures were proposed for canned salmon they may probably be used with other canned-fish products. The following instructions have been abstracted from their report:

Description of Parcel. This should be complete as possible, including the species of salmon, the brand and label, the name of the packer, the name of the cannery, the

132. Cameron. 1937. J. Assoc. Off. Agr. Chem. 20, 432.

size of the can, the can mark, the case mark, the number of cans or cases, and the exact location of the parcel, with any other data which may be of use in identifying that particular lot of salmon. It is also a good practice to keep copies of the label and to file one with the report. Special attention should be given to the code marks on cans; if different markers were used that fact should be mentioned.

Sampling. Attempt should be made to secure a representative sample by taking one or two cans from a considerable number of cases. Sampling of such products is not easy. If the cans were coded, the problem might not be so difficult. With uncoded packs, some system must be worked out which will permit a representative selection of cans.

When the cases are opened for sampling, they should be examined for swelled, rusty, or leaky cans as well as for the condition of the lacquer and labels. "Swells," "leakers," and badly dented or other obviously abnormal cans should not be included among ordinary samples but percentage of such cans should be determined by careful inspection of all cans in the case. If examination of half of the cans selected from large parcels are found to be of high quality, the remaining half should be retained for a time. These may be used later for checking results of examination and for settling differences of opinion. Not less than 24 to 48 cans should be cut.

Bacteriological and Microscope Examination. A suitable percentage of cans should be examined bacteriologically for presence of living microorganisms. Usually one case of 48 cans is examined if the parcel consists of 1,000 cases or less, but the number tested naturally varies with the quality and character of the salmon, the destination of the shipment, and the information desired. Since the results of careful physical examination of the salmon is of great value in interpreting bacteriological results, the same cans should be used for both tests. If possible it is desirable to incubate 24 or more cans at 30°C.(86°F.) for a week or 10 days to observe whether "swells" or "springers" appear.

Technic of Taking Cultures. The tops of the cans are carefully cleaned with a disinfectant and sterilized with a gas flame. After cooling, the vacuum is taken and the can immediately pierced with a hot brad-awl about the size of a small lead pencil. Through this opening samples of liquor containing small pieces of flesh are drawn by means of a large pipette and inoculated into suitable nutrient media. The inoculated plates and tubes are usually incubated at 30°C.(86°F.) for 48 to 72 hours before being examined. After that they may be incubated for an additional 48 hours at 55°C.(131°F.) to test for presence of heat-resistant, thermophilic bacteria.

Direct Microscope Examination. Such examination of the liquor is sometimes of value; one may often determine immediately whether active spoilage is present. Results of this method are often of value for confirming results of physical and chemical examinations.

Interpretation of Results. The unusually high processing temperature used in processing salmon precludes the possibility of survival of any but most resistant spore-forming bacteria. When cocci or nonsporeforming rods are present, it is probable that they gained entrance to the can through a leaky gasket or other similar leak. Of course, they may be present owing to gross understerilization. By far the most common organisms found in canned salmon are the harmless, heat-resistant, aerobic, spore-forming bacteria. Anaerobic bacteria which cause intense putrefaction are more rarely found and if present usually form gas and cause swells which are eliminated at the cannery. The bacterium which causes botulism has never been found in commercially canned salmon and it is believed that the usual cook of 115.6°C.(240°F.) for 90 minutes is a safe one to use. Since the bacteria usually found in canned salmon are harmless, unless they cause spoilage within the can, their presence can be of but little significance. Both aerobes and anaerobes, when present, are usually in the form of inactive or dormant spores and do not multiply greatly within the can, owing to the unfavorable environment or unsuitable food substances present. Occasionally incipient bacterial spoilage without the production of swells is found in canned salmon, though it is not at all common.

Molds and yeasts are very seldom found in canned salmon, except in leaky cans. Uncooked salmon is decomposed principally by the active bacteria of the colon aerogenes

group, though many cocci and other types may be present. These bacteria usually form gases composed of carbon dioxide and hydrogen, and sometimes other products, such as indol. By bacteriological examination of a large number of empty cans and salt obtained at salmon canneries, it has been found that they contain many spore-forming and other kinds of bacteria, yeasts, and molds usually such as are normally present in soil, dust, and air. It is believed that most of the sporeforming bacteria found in non-sterile cans of salmon are introduced in this way.

SARDINES

The sardine industry is well established in many parts of the world. Packing sardines, according to the practice in Maine, has been carefully studied and discussed by Weber.¹³³ This fish derives its name from the island of Sardinia about which it was originally found. The name is now applied to various species of small fish which are canned.

Considerable spoilage may occur in the packing of sardines. Much of it is of bacteriological interest. One great source of trouble in the sardine industry is what fishermen call "feedy" fish, *i.e.*, fish which are gorged with food at the time of catching. Such fish go to pieces quickly after removal from water, while those with little food in their stomachs keep much longer. The best method of coping with this difficulty is not to attempt to pack such fish, to eviscerate the fish before packing, or to allow the food to be digested before packing.

The fish packed in Maine as sardines are caught in weirs which are placed in shallow water. From the weirs they are seined and transferred to the fishing boats. The fish are salted in the boat at the rate of 190 to 450 pounds of salt per hogshead (about five barrels) of fish. If the salt is added dry, it draws out the water. When the fishing boat has arrived at the cannery, the fish are taken by means of different devices to the pickling room where they are stored in brine of a strength depending somewhat on that used on the fishing boat. From the pickling solution they are passed to the flaking machine, the fish usually remaining intact. They are evenly distributed on the flakes which are wire screens about three by two feet. On these flakes, they pass through the rest of the steps to the can. The flakes with fish are then steamed for 10 to 15 minutes in a steam chest after which they are taken to a drying room. If the sardines are to be fried in oil, they are not steamed but are dried as usual. From the friers they are taken to the packing room where, after the heads have been removed, they are packed into cans. Oil is then added, either by a special machine, or by a special attachment on the closing machine. Various types of oil are used, cotton seed, olive, etc., depending on the quality of fish which is being packed. After sealing, the cans are processed in boiling water for a varying length of time of from one and three-fourths to even two and one-half hours. Hovden¹³⁴ described a different procedure for canning California sardines. The fish are cleaned and thoroughly washed in running salt water. They are not salted. They are thoroughly dried in trays and thoroughly cooked in ovens. All California sardines are pressure processed. Another description of the methods of packing was published

133. Weber. 1921. U. S. Dept. Agr. Bull. 908.

134. Hovden. 1923. The Canner, Jan. 20, 1923.

by Beard.¹³⁵ Lang⁷³ observed progressive increase in the number of bacteria in sardines as they were prepared for the can. In the cutting room where are located both the receiving and brining tanks the fish were usually heavily contaminated. After that the number of bacteria decreased. No true aerobic thermophilic bacteria were observed by Lang. Four main sources of contamination were sea water, air or dust, raw materials, and the empty container. Coliform bacteria were present in sea water. These organisms were believed to originate in the polluted water from which the fish were taken. They were never found in the intestines of the fish.

Processing of Canned Sardines. In his extensive description of the packing of Maine sardines, Weber¹³³ gave special attention to processing or sterilization. The sealed cans are processed in tanks of boiling water for one and three-fourths to two and one-fourth, sometimes two and one-half hours, according to the individual packer's idea of the time necessary for sterilization. One or two canneries give the cans a pressure cook in retorts of 110°C. (230°F.) for 30 minutes. This does not seem to affect the quality of the fish. Esty¹³⁶ reported experimental work carried out to determine the proper pressure cook for sardines packed in oil and mustard. Esty inoculated the cans with an organism which had been isolated from swelled cans of sardines. Cans inoculated with 1,000,000 spores gave 100 per cent swells after process at 100°C. (212°F.) for 210 minutes, 100 per cent swells in cans containing 10,000 spores and processed at 100°C. (212°F.) for 180 minutes. Temperatures of 107.2°C. (225°F.), 110°C. (230°F.), and 115.5°C. (240°F.) gave sterile cans.

Microbiology of Canned Sardines. Not many investigations have been carried out on the presence of viable bacteria in canned sardines. Obst¹³⁷ found a bacillus possibly identical with *Bacillus walfishrauschbrand* in pure culture in 287 cans of swelled sardines. Koch's postulates were satisfied. using this organism and sound cans of sardines. The organism was an aerobic, gas-producing, nonsporeforming bacillus. Obst inoculated it into cans which were then processed according to the usual factory methods and temperatures. She was able to fulfill Koch's postulates with the above-mentioned organism and believed that it was identical with Nielsen's¹³⁸ organism. It was reported to be quite resistant and to survive boiling for one and one-half hours under the conditions of the experiment.

Weber had an opportunity to study the cause of "swells" in sardines. It soon became evident that the cause of swells in cans and also the so-called "belly breaking" of "feedy" fish was bacteriological. Weber found no aerobic bacteria in swelled cans of sardines, but *Bacillus walfishrauschbrand* Nielsen, a rapid sporeformer, was isolated in pure culture. This organism, according to Weber, was an organism found by Nielsen in whales made sick by being shot with arrows previously inoculated with material from dead whales. Weber also found another organism called *Bacillus B*. This organism was pathogenic to mice and guinea pigs and produced about

135. Beard. 1926. *Canning Age*, April, 1927.

136. Esty. 1925. *The Canner*, March 7, 1925.

138. Nielsen. 1880. *Centbl. Bakt.* 7, 267-271.

the same decomposition as that produced by Nielsen's organism. It did not, however, form spores and was, therefore, much less resistant to heat.

Sadler¹³⁹ and his colleagues have published several reports on the spoilage of canned sardines. Most of their organisms seemed to be of the colon-aerogenes type. *Bacillus vulgaris* Hansen was also found. The fish seemed to be infected during packing. Cathcart¹⁴⁰ found bacteria of the coliform type in cans of sardines which gave off gas when they were opened. Sadler, in general, confirmed the conclusions reached by Weber.¹³³ The National Cannery Association at its Eastport, Maine, Laboratory under the direction of Bartlett,¹⁴¹ carried on some bacteriological studies on sardines. They were able to confirm Obst's conclusions. Bartlett stated that most of the swells of canned sardines were caused by members of the *Escherichia coli* group. These organisms were isolated from fish which were distended with gas as well as from pickle in which "feedy fish" were lying.

A recent survey of sardine canning in Maine by Highlands and Williams^{139a} revealed a small number of bacteria in and on the fish and absence of heat resistant types. Anaerobes occurred irregularly and were not numerous. Eight per cent of salt was observed to inhibit bacteria over a commercially practicable holding time. These observations explain why spoilage troubles are infrequent in the Maine sardine canning industry.

Relation of *Clostridium botulinum* to Fish Canning. This organism is a constant threat to the canning industry, and information as to its presence in raw materials or on articles used in canning is always pertinent. Lang⁷³ observed it in slime of tuna. Type A toxin was observed in cultures from fish slime and the cleaned fish just before canning. Lang also found *Clostridium botulinum* in washings of empty sardine cans; one per cent of cultures made from washings of 200 sardine cans showed presence of Type A toxin.

Heat-resistance studies on *Clostridium botulinum* by Lang showed considerable variation among the products used. The following results were reported.

Product	Destruction time at 121.1°C. (250°F.) in minutes
Abalone.....	1.57
Kamaboko.....	8.97
Mackerel in brine.....	2.44
Sardines in brine.....	2.34
Sardines in mustard sauce.....	6.55
Sardines in oil.....	8.00
Sardines in tomato sauce.....	3.66
Shad.....	1.58
Shad roe.....	5.61
Squid in ink.....	0.69
Tempra.....	6.17
Tuna in oil.....	6.95

In oil packs, resistance of *Clostridium botulinum* to heat was much greater. Lang attributed this to differences in the rate of heat penetration into oils over that of moisture alone or a mixture of moisture and oil as well as to the subsequent trapping effect of the oil. Suggested processes for canned-fish products, which will not be presented here, were suggested by Lang.

Sour Pickling or Marinating of Fish. Much fish is pickled in vinegar and a wide field has been opened up. Abst¹⁴² discussed this food, both from the standpoint of flavor as well as keeping quality. The fish is thoroughly washed before salting and addition of vinegar. Better results were secured when the vinegar was boiled and the containers sterilized. Herring is most used in the marinating industry. Abst stated that the first requirement in the preparation of Bismarck herring was to thoroughly cleanse the fresh fish in water and remove the scales. The fish are then drained, the heads cut off, and the entrails removed. The fish are washed in running water again, and carefully drained, then put into a five to six per cent vinegar pickle, containing considerable salt. They remain in this pickle for three to four days, depending on the size. They are then placed in sterilized boxes with the addition of mustard seeds and peppercorns between the layers. They are then covered with a two to three per cent vinegar, containing sugar. The cans are immediately soldered.

Hiedewohl and Henneberg¹⁴³ examined swelled cans of marinated herring, finding only acetic acid bacteria with no sporeformers or putrefactive bacteria. In some cases, swells were due to hydrogen, resulting from the action of acid on the metal of the container. Addition of at least two per cent of acetic acid to the liquor was said to be necessary to prevent spoilage by lactic acid bacteria.

SHELLFISH

Since shellfish of various kinds are usually harvested from polluted water they may be public-health problems. The evidence on this point is now accepted. They have been responsible for many outbreaks of typhoid fever and other similar infections. Some of these are discussed in the paragraphs immediately to follow. The significance of this problem is emphasized when it is remembered that the cases of communicable disease caused by them are not confined to the areas where the shellfish are harvested but may extend to great distances inland. Such has been the case with oysters. Stiles¹⁴⁴ reported that cooking would not always destroy objectionable bacteria when they were present. Cooking will not destroy many saprophytic bacteria in fish muscle.

General Sanitation in the Shellfish Industry. For many years practices were permitted in the shellfish industry which did not promote distribution of a sanitary product. In 1932 a committee¹⁴⁵ of the American Public Health Association pointed to the need for improved sanitation of the

sea-food industry. They mentioned the necessity for prompt and careful handling of the shellfish and need for proper equipment. Since these early discussions much progress has been made as indicated below under the several types of shellfish.

OYSTERS

On account of the unsanitary conditions of water in which oysters are raised, their control has been a constant problem for health officials. The comprehensive publication by Hunter and Harrison¹⁴⁶ reviews these problems, and Orton¹⁴⁷ has shown how the physiology of the oyster is related to its function in disseminating pathogenic bacteria. Care must be used in generalizing with respect to sanitary quality of oysters from results of water analysis. While the sanitary quality of oysters agrees generally with the quality of water, Fisher and Asker¹⁴⁸ did not observe a strict relationship. Both were better in the winter.

Significance of Oysters in Dissemination of Disease. About 1880¹⁴⁹ Sir Charles Cameron, health officer of Dublin, discussed relation of oysters to typhoid fever before the British Medical Association. Little attention was given the subject until 1895 when Sir William Broadbent attributed cases of typhoid fever to contaminated oysters. Conn,¹⁵⁰ in a fine epidemiological investigation in the United States, proved to the satisfaction of those interested in public health that an outbreak of typhoid fever among those who had attended a fraternity banquet at Wesleyan University was caused by infected oysters. The chain of evidence was so complete that the relation of insanitary oyster beds to disease was established. Since that time many similar investigations have confirmed Conn's work. Among them were investigations by Klein,¹⁵¹ Fuller,¹⁵² Digby and Shenton,¹⁵³ Phelps,¹⁵⁴ Gorham,¹⁵⁵ Stiles,¹⁵⁶ Joseph,¹⁵⁷ and many others. In the United States relation of oysters to disease dissemination was not known until Conn did his work. Stiles¹⁵⁶ gave an extended bibliography of contributions to the subject in his publication. Even though it is definitely known that oysters may harbor *Eberthella typhosa*, outbreaks of typhoid fever continue to be traced to them. Banks¹⁵⁸ reported 42 cases of typhoid fever in San Diego, California, from polluted oysters. The etiologic significance of oysters may often be overlooked, especially in inland cities. Brooks¹⁵⁹ reported 50 cases of typhoid fever as due to oysters. Earlier contributions had been made by Pease,¹⁶⁰ Soper,¹⁶¹ and Stiles.¹⁶²

The largest and best-known outbreaks of typhoid fever caused by oysters were those in Chicago and New York City in 1925. The great prevalence of typhoid fever in these cities from oysters caused a conference to be called by the Surgeon General of the U. S. Public Health Service in Washington, in February, 1925.¹⁶³ Over 150 delegates, consisting of health and food officials and representatives of the oyster industry from 28 different states, convened. The conference arrived at resolutions which, if obeyed by oyster growers and shippers, would make oysters better and safer for use as food.

Bundesen¹⁶⁴ reported a study of an apparently oyster-borne outbreak of typhoid fever in Chicago involving 129 verified cases. The epidemiological evidence seemed very convincing that oysters were the cause. Bundesen stated that the New York City outbreak had started about two weeks before. According to Bundesen, blue point oysters were the cause of 65.1 per cent of cases of typhoid fever in Chicago. Part of the epidemic in New York concurrent with the Chicago outbreak was probably due to the same lot of oysters. Harris¹⁶⁵ summarized the characteristics of the New York City oyster-borne typhoid-fever epidemic as did Lumsden, Hasseltine, Leake, and Veldee¹⁶³ in Supplement 50 of the Public Health Reports. To prevent further outbreaks of typhoid fever from oysters, Harris advised that greater attention must be given to sources of oysters and the conditions under which they are shipped and handled.

Numerous bacteriological investigations have been reported to convince one of the danger. Fuller¹⁶⁶ carried out observations on oysters in Narragansett Bay. The sewage of the city of Providence, which amounted then to about 14,000,000 gallons per day, was discharged into Narragansett Bay and carried out by the tide, coming into more or less contact with some of the oyster beds. Samples of water and oysters were collected from different localities, and analyses were made of the material while still quite fresh. The results showed that the water, oysters, mussels, and clams for a distance of a quarter of a mile from the sewer opening contained *Escherichia coli* and *Aerobacter aerogenes*. The water and oysters from a bed two miles below the sewer contained the same organism. Thirty per cent of the oysters and about 60 per cent of the water samples from a bed situated in a strong tidal current five miles from the sewer contained *Escherichia coli*. Forty per cent of the oysters and 70 per cent of the water samples from a bed in sluggish water five and one-fourth miles from the sewer contained the bacteria, and oysters from a bed six miles were also infested.

Purification of Oysters. The fact that oysters may often be harvested from polluted waters makes it necessary to subject them to purification procedures several of which yield a satisfactory product. Dodgson¹⁶⁷ believed that sewage pollution seriously prejudices the oyster industry. Since

163. Lumsden, Hasseltine, Leake, and Veldee. 1925. Pub. Health Rpts., Sup. No. 50.

167. Dodgson. 1930. Rev. in Biol Abs. 6, 2323.

it is impracticable to eliminate it, the solution seems to lie in purification under government control such as is carried out in England and other countries. Purification is accomplished largely by physiological functioning of the shellfish in sterilized water. They are not exposed to chemical disinfection until purification is completed, when they are immersed for one hour in water containing three p.p.m. of active chlorine. The rationale of purification depends on immobilization of sewage bacteria in the mucoid discharges of the shellfish. The shellfish circulate the water in the tanks many times through their gills during purification, filtering out and immobilizing any bacteria originally free in the water. For this reason sterilization of the water is not essential but is practiced as an added precaution. Dodgson established a standard of purity of not more than five coliform bacteria per milliliter of shellfish substance. Regulations have been enacted in England¹⁶⁸ to protect the public from contaminated oysters. If sanitary inspection of the oyster grounds indicates that the shellfish are polluted, they must be purified by an acceptable method. The American Public Health Association¹⁶⁹ passed a resolution against water storage cleansing, or conditioning of shellfish in certified bodies of water which do not at all times meet the U. S. Treasury Department standards for drinking water. Natural bodies of water which are subject to constant pollution should not be used. In other words, only water of high sanitary quality shall be used.

The splendid work of Dodgson¹⁷⁰ on purification of shellfish has been referred to at various places in this chapter. On several occasions he has described procedures which are employed by the Ministry of Agriculture and Fisheries in Great Britain for control and purification of edible oysters and mussels. Although reference will be made in other places to his work, a general summary of these methods may be given here.

“Oysters and mussels harvested from polluted water areas as a result of extended experimentation are spread on wooden grids in large concrete tanks, hosing them thoroughly at the start, midway, and at the end of the process. They are exposed for two successive periods of 24 hours to water sterilized by chlorine but from which all trace of active chlorine has been removed by sodium hyposulphite, and finally sterilizing the shells by a bath of water containing three p.p.m. of active chlorine. In winter time the oyster baths must be heated artificially to about 54°F., as oysters will not function at the colder water temperatures. The actual purification of the oyster body is, therefore, done by the shellfish themselves flushing out the impurities by means of the sterile water ingested. It was found that chlorine, various hypochlorites, and chloramines interfere with normal functioning and elimination and either prevent or interfere with purification in some degree. Hence the shell sterilization bath is delayed until treatment is complete. This two-day self-purification procedure reduces the lactose-fermenting bacteria from some hundreds or more per ml. to from 0 to 5 per ml. from which the required standard came to be established of not more than five lactose-fermenters per ml. Extended bacteriological examinations demonstrate that the above procedure affords a ready method of meeting the standard requirements and had eliminated the transmission of disease through the eating of contaminated shellfish. A considerable discussion of various phases of the bacteriological findings is given, including the natural multiplication of lactose fermenters in polluted sea water and tank water, the advisability of

168. Bull. Hyg. 10 (1935), 137.

169. Amer. Pub. Health Assoc. Year Book, 1937-1938, 36.

170. Dodgson. 1937. Pub. Health 50, 279-284.

conducting the tests at 42°C. or 44°C. instead of at 37°C. and the possibility of multiplication of organisms of the typhoid group in water. The author stresses his view that topographical observations, properly carried out must provide the real criterion of the safety of shellfish growing areas. In other words, the possibility of pollution of the layings is the essential matter and bacteriological examinations are merely ancillary, often unnecessary, and not infrequently misleading."

Floating. For years oyster growers placed oysters in fresh water in order to remove salt and to cleanse them. The Bureau of Chemistry about 1909 investigated this practice and insisted that such oysters should be labeled "Floated Oysters." In June, 1927, the Bureau of Chemistry prohibited the shipment of floated oysters. (See Food Inspection Decision 110.) Nelson's¹⁷¹ work seemed to favor the practice of "floating" oysters, which was widely prevalent in the North. Oysters are kept on submerged floats in water with less salt than that of the beds; during this time they draw in water as they do in the original beds. This process is called "floating," "giving the oysters a drink," "freshening," and "fattening." The resulting advantages are said to be removal of the mucous, increased volume of the flesh of the oyster, improvement in color and texture, decrease in amount and rapidity of shrinkage, and better retention of water content in transport and storage. In the experiments reported by Nelson, half of the sample from each bed was floated, then compared with the half not so treated. The results of 25 selected experiments were presented. Except in the case of certain ones injured in handling, oysters were found to regulate the amount and quality of the water they "breathe," opening only when the incoming tide brings water containing a certain proportion of salt and refusing to open in fresh water. The process of floating enabled the oysters to rid themselves of the dirt brought from the beds, hence the floated product appeared cleaner. An improvement in color was also noted. When unfloated oysters were shucked in comparison with floated ones, and the two lots were left a few hours in their natural liquor, the former secreted liquor more rapidly, and also considerable slime, in which the coarser part of the dirt becomes entangled. This slime became stringy and the liquor turbid and repulsive, owing to the dirt that was mixed with it. In strong contrast, was the clean and appetizing appearance of the floated lot; here, at first, the liquor was rather small in amount, but as much as in the former cases was finally pressed out through contractions of the tissues. It seemed that the total slime in the two cases was finally approximately equal, though at the start the floated lot seemed to be the more slimy. It was claimed that no deception is involved in the process, since it seems to be impossible to improve the appearance of a poor oyster by it. Water entering the tissues, as it does in the process of floating, is more firmly retained than that held by capillary attraction in the channels of the body, and much more firmly retained than that between the oyster and the shell. This retained water, the author believed, improves the keeping and cooking qualities. No significance was attached to the loss of flavor, as this is said to be due merely to loss of salt which can easily be replaced before serving. It appears to be impossible to have the floats near the beds, or at least it is much more convenient to have them near the storehouses. Nelson concluded that the practice of floating is not injurious if the water in which the oysters are floated is pure, and that the practice is desirable on account of the improvement in the oyster. It was suggested that both floated and unfloated oysters be admitted to the market, since a demand for both kinds exists, and in time the demand for the floated product will be so great as to give it the greater value. Nelson noticed that the experiments were rather limited and that a more prolonged study of the question was desirable. Bodin¹⁷² and Fabre-Domergue¹⁷³ floated oysters in tanks through which artificial sea water was pumped. They believed that oysters were purified as quickly in this manner as when floated in natural sea water.

A fairly complete bacteriological study of the process was made by Krumwiede, Park, Cooper, Brund, Tyler, and Rosenstein.¹⁷⁴ Lightly and heavily contaminated oysters

were used at temperatures high enough to ensure active drinking by oysters. They were placed in natural waters, i.e., ensuring very great changes in the water from tidal flow. Under such conditions oysters native to the water cleared themselves of typhoid bacilli between the 11th and 24th days; oysters obtained from relatively distant waters, between the 9th and 16th days. The original contamination with typhoid bacilli was obtained by causing them to drink in sea water containing feces contaminated with this bacillus. Another experiment with sea water showed that *Eberthella typhosa* may survive in sea water between 19 and 24 days. From their experiments Krumwiede and his colleagues concluded that oysters contaminated with *Eberthella typhosa*, when actively drinking in their natural habitat, become noninfectious in three weeks. Consequently, they believed that an ordinance allowing the transfer of oysters from doubtful waters to clean waters during the closed season, with the provision that no dredging in the latter waters be allowed for a period of four weeks after the transfer, covers observed facts and gives a reasonably generous margin of safety.

An experimental plant for conditioning oysters was built in Norfolk by Messer and Reece.¹⁷⁵ About four gallons of water per bushel of oysters were needed per hour at a water temperature of 10°C.(50°F.); at lower temperatures less water was needed. Results of five bacteriological samplings showed reductions of not less than 95 per cent in 30 hours at a temperature range between 9.4°C.(49°F.) and 11.7°C.(53°F.). Messer and Reece believed that conditioning in tanks was possible with modern equipment and proper methods. Good results were reported by Tohyama and Yasukawa¹⁷⁴ by transfer to uncontaminated water. Even in sea water slightly polluted they reported a reduction of 500 million *Escherichia coli* to 41 in three and one-half days. In naturally infected oysters the *Escherichia coli* score is usually under 500 and rarely beyond 2,000 to 2,300; such oysters will cleanse themselves more rapidly. In clean water Tohyama and Yasukawa thought a stay of 24 to 48 hours was sufficient.

Transplanting. Oysters are frequently transplanted from the beds in which they have been propagated into clean water free from sewage. It has been found that they cleanse themselves in a short time. In polluted water objectionable bacteria may reach the intestinal tract; when the oyster is placed in pure water these are washed out. The rapidity of the cleansing process depends on various conditions. Studies on the rate of purification have been made by Round,¹⁷⁷ Phelps,¹⁷⁸ Bulstrode and Klein,¹⁷⁹ Johnstone,¹⁸⁰ and others.

Gorham¹⁸¹ pointed out that there is a seasonal variation in the bacterial content of oysters, which should be considered in sanitary work. Oysters collected from one bed in February scored zero, while those collected in May scored 100. From the experimental data presented, Gorham concluded that in warm weather the results of bacterial analyses of oysters "tally very well with the actual conditions as determined by the sanitary survey and, therefore, analyses may be used to determine whether or not certain oysters may be sold for human consumption." But during the cold weather, oysters judged by analyses alone would be pronounced good although they came from within a short distance of a larger sewer outfall. During hibernation, according to Gage and Gorham,¹⁸² oysters tend to purify themselves. Hibernation was defined as a slowing down of biological activity as a result of a reduction of temperature. It has been shown by several different investigators that as the temperature approaches the

freezing point the shells of the oyster tend to close and remain closed for the greater part of the time. Gage and Gorham secured further evidence on this phenomenon, and while their data supported the general findings, there were discrepancies which suggested a number of different explanations. One was that oysters might become carriers of *Escherichia coli*. On this question, Wachter¹⁸³ stated that oysters from polluted sources might give high scores during the seasons of warmer water and low scores when the water is colder. Consequently, Wachter did not regard low scores during the hibernating periods when the oysters were from polluted water, with the same assurance as low scores for oysters from a non-polluted bed. Wachter also stressed the need for frequent sampling of a bed, since one examination might not indicate its real sanitary condition. Laboratory examinations are liable to be influenced by a number of different factors.

Krumwiede *et al.*,¹⁷⁴ after finding that *Eberthella typhosa* could live for about two weeks in oysters in their natural waters, asked how these data should influence the minimum time that should be required for oysters to remain in clean waters when transported from doubtful sources. They also asked about the effect which the infected oysters would have on oysters in the beds to which they were transported. The Department of Health of New York City allows no dredging of beds to which doubtful oysters have been added for 30 days thereafter. Taking into account a number of facts, it was concluded that three weeks was a sufficiently long time for contaminated oysters to purify themselves. However, it was stated that an ordinance allowing the transfer of oysters from doubtful waters to clean waters during the closed season with the provision that no dredging in the latter waters be allowed for a period of four weeks after the transfer, covers observed facts and gives a reasonably generous excess margin of safety.

Chlorination. The value of chlorine as an agent in the disinfection of water, vegetables, fruits, etc., suggested its use as a sterilizing agent for oysters. Wells¹⁸⁴ has stated that the use of the chemical is now a well-established practice. Some of the pioneer work on the subject was done by Wells. In 1916, he carried out experiments which seemed to indicate that treatment with hypochlorite caused a very satisfactory degree of purification. Exposure for a short time in water containing calcium hypochlorite brought about such purification that the oysters passed the most rigid standard. In 1923, a practical purification plant was described.

This method may be applied under careful regulation to the treatment of many oysters. However, oysters which are heavily polluted before treatment should be so handled that there is a greater safety factor before they are sold to the public. He stated that no oysters scoring higher than 230 or 320 should be purified by this method. With oysters with a higher score, an insufficient margin of safety was allowed. A similar position was assumed also by Krumwiede *et al.*,¹⁸⁵ who reported that chlorine did not rid oysters of all of the contaminating typhoid bacilli, even when amounts of chlorine, times of exposure, and times of drinking or flushing

185. Krumwiede *et al.* 1926. Amer. J. Pub. Health 16, 142-152.

were made in excess of those recommended by the New York State Conservation Commission. Krumwiede and his co-workers believed that the best procedure is to grow oysters in uncontaminated water rather than to have to treat contaminated oysters to make them safe. Less satisfactory results were reported by Yasukawa.¹⁸⁶ He found that much of the free chlorine was used by organic matter and was thus not available for destruction of bacteria in the oyster. While *Eberthella typhosa* and *Escherichia coli* mixed with sea water containing as little as one p.p.m. of available chlorine were destroyed in less than five minutes, Yasukawa found it impossible to sterilize oysters immersed for 24 hours in sea water mixed with either of these bacilli even when 500 p.p.m. of chlorine were used. The usual experience was diminution for about 96 hours, after which little change occurred. In more than 50 p.p.m. of chlorine oysters will not respire at all. For these reasons Yasukawa believed that it was better to flood oysters with chlorinated sea water.

Ozonized Water. The little work which seems to have been done on sterilization of shellfish with ozonized sea water indicates considerable success. In investigations by Violle and Rose¹⁸⁷ and Salmon, LeGall, and Salmon¹⁸⁸ the latter found that in a period which is certainly less than four days and probably less than 48 hours shellfish, even if grossly contaminated with pathogenic bacteria, are rendered completely sterile and safe for consumption. No harmful substances were formed and no alteration in flavor was caused by the treatment. Violle's results were equally satisfactory. Infected shellfish were completely sterilized by exposure to ozonized water.

Microorganisms in Market Oysters. The microorganisms present in unpolluted oysters are probably from the water from which the oysters were taken. The first important information to seek and consider is whether oysters from unpolluted areas contain *Escherichia coli*. When an algebraic sum is taken from the available experimental data, one must conclude that this organism is probably not present in unpolluted oysters. Consequently, there is some justification in using it as an indicator of pollution. Phelps¹⁸⁹ concluded from experimental studies that within four days, and possibly within a shorter period of time, a healthy oyster transplanted from polluted to clean waters will rid itself of the evidences of pollution, and argued from this that sewage material which is always associated with *Escherichia coli*, and of which the latter is taken as an index, would also be eliminated. In further tests, such very rapid improvement was shown within two days that there was no reasonable doubt as to the efficacy of very short periods of storage in clean water. Joseph¹⁹⁰ carried out an investigation to determine whether the oysters sold in Baltimore contained organisms derived from the human intestinal tract and whether or not their bacterial content varied with the season of the year. The results of

the examination indicated the quality of the oysters at the time they were sold and not when collected. The methods of examination were those adopted by the committee of the American Public Health Association on standard methods of shellfish examination. The results indicated that the oysters sold in Baltimore were, as a rule, free from sewage contamination. It was found that in the early fall and in the spring the bacteriological content of oysters was high, while in the cold winter months the bacterial content was low. Results of an investigation by Eliot¹⁹¹ showed in shucked and shell oysters, kept at laboratory temperature, a marked increase in numbers of *Escherichia coli* in 14 days. The bacteria of the decomposing oyster may be divided into five principal groups: (a) the colon aerogenes group; (b) the streptococci; (c) the "water bacteria," including members of the green fluorescent, the yellow pigmented, the nonpigmented groups, and vibrios; (d) the anaerobes; and (e) the incidental organisms, such as the chromogenic cocci and the aerobic sporeformers.

Since Eliot failed to state the age of the oysters with which he worked, Bacon¹⁹² conducted additional experiments. Bacon collected 400 oysters and held them at 21 to 24°C. (69.8 to 75.2°F.). Scores were determined each day by Standard Methods. An appreciable increase in scores and total counts was observed, thus confirming Eliot's work. Bacon then stated that scores and counts would be misleading, unless they were determined on fresh samples.

A study of the bacterial flora of market oysters was made by Geiger, Ward, and Jacobson¹⁹³ during the Chicago epidemic of typhoid fever, caused by oysters, in 1924. No *Eberthella typhosa* were revealed to be present in 784 samples of shucked oysters and 328 samples of shell oysters. Various bacteria were identified, among which were 81 strains closely related to the typhoid group; *Escherichia coli* were, of course, found. Oysters were said to be potential factors in certain infections. Some 11 years later Geiger and Crowley¹⁹⁴ isolated *Staphylococcus aureus* from oysters from the Pacific Northwest. Except for one place no sewage pollution was apparent. By means of intraperitoneal inoculation into kittens, some of the strains were shown to be mildly toxic. Epidemiological findings confirmed the laboratory results.

Escherichia coli is a bacterium used to indicate the sanitary conditions of the grounds from which the oysters are taken. The behavior of this organism in stored oysters is therefore of considerable importance. Tonney and White¹⁹⁵ determined the *Escherichia coli* scores of oysters on successive days during storage at 5 to 8°C. (41 to 46.4°F.). The percentage increase in the score of one lot was 458 in 12 days and of another lot 1,490 in 11 days. Shucked oysters collected in the early part of the season and stored at the above temperatures increased more rapidly in *Escherichia coli* content than oysters gathered in midwinter and stored under similar

conditions. Living shell oysters did not improve in *Escherichia coli* content under dry storage conditions at the above-mentioned temperatures from the 11th to the 83rd day after shipment. After the 28th day a consistent decrease was noted, and after the 60th day the tests for *Escherichia coli* were usually negative. A study of 856 samples of shucked oysters received on the Chicago market showed that 71 per cent would have passed an *Escherichia coli* score of 140; 97 per cent of shell oysters passed a score of 50, while all of 164 samples of clams passed the same score. In view of these results Tonney and White believed that an *Escherichia coli* count of not to exceed 140 for shucked oysters and not over 50 for shell oysters and hard-shelled clams could be recommended. These counts were later adopted as official for Illinois markets. Perry¹⁹⁶ also recognized the possible value of *Escherichia coli* as an indicator of pollution of oysters. He did not believe, however, that pollution tests suitable for drinking waters were equally applicable to shellfish (Perry¹⁹⁷). Determinations of presence of members of the coliform group could be quite unreliable and may not, under certain circumstances, indicate fecal pollution. Determination of presence of *Escherichia coli* was considered to be a much better index of pollution both in shellfish and the water from which they come. In both of the above-mentioned papers by Perry much discussion is given to tests that might be used. Cellobiose fermentation was looked on with favor as was the Eijkmann Test.

Results of extensive bacteriological examinations are not necessary to show the value of low storage temperatures for oysters. Tanikawa¹⁹⁸ found that at $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$) the bacterial content of oysters remained approximately constant for 24 days. At $0^{\circ}\text{C}.$ ($32^{\circ}\text{F}.$) there was a gradual increase, resulting in a five-fold rise, in the same time. At $5^{\circ}\text{C}.$ ($41^{\circ}\text{F}.$) the number of bacteria increased about a thousand times. These experiments were made on minced oysters. Whether this would make a difference is difficult to state.

Reddening of Oysters. Earlier in this chapter the reddening of cod was discussed. A similar trouble exists in the oyster industry, which renders oysters unsightly and unfit for food. Hunter¹⁹⁹ isolated a yeast as the etiologic agent in the spoilage. It was found to be widely distributed in oyster houses and on utensils in and about the houses. The yeast formed a pink pigment. No ascospores were formed.

Bacteria in Decomposing Oysters. Investigations of the microorganisms concerned in spoilage of oysters have been reported by Hunter and Linden.²⁰⁰ The bacteria were arranged in three groups: (1) types which, upon inoculation into artificially purified oysters or into oyster infusion media, produced foul, putrefactive odors; (2) types which produce acidity or sourness; and (3) types which were inert. In the first group fell bacteria of the genera *Serratia*, *Pseudomonas*, *Proteus*, *Clostridium*, and *Bacillus*.

200. Hunter and Linden. 1925. Amer. Food J. 18, 538-540; J. Agr. Res. 30, 971-976.

In the second group, *Aerobacter aerogenes* and *Aerobacter cloacae* were found throughout the culture period of spoilage. *Escherichia coli* and *Escherichia communis* were found during the early stages and streptococci, lactobacilli, and yeasts during the late stages when the hydrogen-ion concentration was between pH 5.0 and 4.6. The organisms of the third group included ordinary bacteria and yeasts. Conclusions reached by Eliot on this subject are quoted above.

Longevity of *Eberthella typhosa* in Oysters. The recurrence of cases and outbreaks of typhoid fever attributed to oysters has made it important to determine how long *Eberthella typhosa* would live in oysters. While the actual number of days reported by the several investigators is different, the conclusions are not far apart.

Herdman and Boyce²⁰¹ floated oysters in water to which typhoid bacilli had been added, and found living bacilli up to 10 days. Field²⁰² stated that there was no decrease in cells of *Eberthella typhosa* and probably a slight increase after oysters had been removed from an infected tank. Klein²⁰³ found that *Eberthella typhosa* survived in oysters from seven to 11 days. He also reported finding the organism in market oysters. Foot²⁰⁴ injected shell oysters with one ml. of broth culture of *Eberthella typhosa* and stored them at 50 to 65°C. (122 to 149°F.). Living typhoid bacilli were found for 30 days.

Kinyoun²⁰⁵ experimented to determine whether oysters contaminated with *Eberthella typhosa* and then stored under usual market conditions would remain potentially dangerous over a sufficient length of time to infect the consumer. The oysters used were large salt-water variety, tonged in Chesapeake Bay and taken to Washington. They were out of the water about eight days before the experiments were started. In the laboratory they were inoculated with two strains of *Eberthella typhosa*. It was found that for 15 days after inoculation *Eberthella typhosa* could be isolated. At this time Kinyoun discontinued his experiments. *Eberthella typhosa* probably does not increase in numbers in the body of the oyster. Herdman and Boyce were of this opinion. In France, Costa, Hovasse, and Boyer²⁰⁶ believed that the role of intravalvular sea water in the transmission of typhoid fever was negligible.

Tonney and White²⁰⁷ infected shucked oysters with *Eberthella typhosa* and stored them at 36.7°C. (98°F.), 21.1°C. (70°F.), and 7.2°C. (45°F.). In the oyster fluid, *Eberthella typhosa* survived in considerable numbers for one, four and 22 days, respectively. Living shell oysters were also infected and stored at 21.1°C. (70°F.) and 7.2°C. (45°F.). At 21.1°C. (70°F.) *Eberthella typhosa* survived in the fluid within the shells for eight days; at 7.2°C. (45°F.), which was said to be the ordinary icing temperature of the trade, the organisms were found to survive for 60

days. The exterior of the shells of oysters exposed for 48 hours to a four per cent sea salt solution containing large numbers of *Eberthella typhosa*, after storage at 7.2°C. (45°F.), showed the presence of typhoid bacilli on the 23rd day. From these data, Tonney and White concluded that the longevity of *Eberthella typhosa* in oyster juice of both shell and shucked oysters varied with the temperature. In general, that temperature which tended to prolong the life of the oyster was also best for prolonging the viability of the typhoid organisms. The findings of Tonney and White that typhoid bacilli could survive 22 days in shucked oysters and 60 days in shell oysters are in general accord with the data found by others. Data reported by Krumwiede, Park, Cooper, Grund, Tyler, and Rosenstein,¹⁷⁴ in general, confirm those reported by Tonney and White. These latter investigators reported that *Eberthella typhosa* survived in oysters for at least nine to 11 days, but were not found on the 16th and 24th days. These data applied to oysters in their natural waters when the temperature was high enough to insure active drinking.

Similar situations were reported by MacLean,²⁰⁸ Lancelin,²¹⁰ and Gordon and Davey.²¹¹ In these cases shellfish from grossly polluted areas caused illness.

Canned Oysters. Food laws of certain states require that oysters be shipped in sealed containers. Consequently they are packed in tin cans, glass jars, or paraffined paper containers. Griffiths²¹² found that vacuum-packing of oysters resulted in a better product and spoilage was delayed.

Frozen Oysters. In an investigation to determine the sanitary condition of market shucked oysters in inland cities Lord²¹³ examined a series of samples of frozen oysters purchased on the Urbana, Illinois, market. These samples had a decidedly low bacterial content and were in sharp contrast to the liquid shucked oysters. Plating methods yielded very low numbers of bacteria and *Escherichia coli* was found in only two samples. The hydrogen-ion concentration was below 5.4 and the oysters gave no evidence of staleness or decomposition.

Sanitary Quality of Market Oysters. Few comprehensive investigations have been carried out. Lord²¹³ examined many samples of shucked oysters purchased on the above mentioned market. In general, he observed an unwholesome condition. The numbers of bacteria, as shown by plate counts, were very high and the *Escherichia coli* content was higher than any standard which has ever been suggested. These oysters probably reflect the condition of oysters served generally in inland cities.

BACTERIOLOGICAL EXAMINATION OF SHELLFISH

Active interest in this subject started in 1910 when a committee of the American Public Health Association presented a report on procedures. Since that time many different individuals and groups have proposed

208. MacLean. 1933. New Zealand Rpt. Director-General of Health.

212. Griffiths. 1937. Special Memorandum No. 2468-G, U. S. Bur. Fisheries, Wash., D. C.

other procedures. These various methods have been reviewed by Lord.²¹³ They will not be reviewed in this book. All of them have been proposed to improve methods which existed theretofore and have used *Escherichia coli* as the indicator of pollution of both the shellfish and shellfish waters.

While sampling is a difficult problem in analysis of many foods, it is especially so with shellfish. Some of the variable results may be attributed to difficulty of securing proper samples.

The Food and Drug Manual, giving instructions to officials, analysts, and inspectors of the Bureau of Chemistry relating to procedure for the enforcement of the Food and Drugs Act of June 30, 1906, gave the following instructions for collecting samples of oysters for bacteriological analysis:

69. *Sampling Oysters in the Shell.* Select a sufficient number of oysters of average size, with deep bowls and shells tightly closed, to represent the shipment. Pack in clean cloth bag or other suitable container. Samples kept over 12 hours before reaching the laboratory should be iced in such a manner as to prevent mixing ice water with the oysters. A metal container inside a tub may be used for this purpose.

70. *Sampling Shucked Oysters.* The stock in the container to be sampled must be thoroughly mixed to obtain an even distribution of the meats and the liquor. This may be accomplished either by shaking and inverting several times or by means of a sterilized ladle. Fill a sterilized pint Mason jar by means of a sterilized ladle or dipper. If more than one container is to be sampled every utensil must be washed and sterilized before being used to sample each additional container. Place the samples at once in a carrying case containing cracked ice, so that the sample is cooled to near the freezing point, and deliver to the laboratory as quickly as possible.

In many of the earlier methods of analysis the oyster was merely cut into small pieces which were then manipulated with sand or glass beads to prepare them for analysis. Better preparation of the sample is secured by a disintegrator such as the mixers used at soda fountains. These prepare a smooth, homogeneous mixture for plating and insure presence of *Escherichia coli* in samples removed for plating and culture in fermentation tubes. Sandholzer, Ferguson, and Berry²¹⁴ found that macerated oyster meat yielded higher bacterial counts than whole oysters. The count was said to be proportional to the degree of disintegration.

American Public Health Association Method for Bacteriological Examination of Shellfish and Shellfish Waters.²¹⁵ This method was proposed by a committee and probably represents the best practice at the time the report was prepared. The term "shellfish" was defined as referring to oysters, soft-shelled clams, quahaugs, and mussels. The coliform group was considered to include all organisms which, upon transfer from a positive presumptive test (gas positive in lactose broth), showed fermentation with gas formation in lactose medium containing .00133 per cent of brilliant green and two per cent of bile (brilliant green lactose bile broth).

Escherichia coli was considered to be any member of this group which in pure culture failed to grow in Koser's citrate medium within 24 hours or which showed definite gas formation in modified Eijkman medium incubated at 45.5°C.(113.9°F.).

I. BACTERIOLOGICAL EXAMINATION OF SHELLFISH-GROWING WATERS

Collection and Transportation of Sample—Samples of water from shellfish-growing areas should be collected at various stages of the tide and should also be collected at

213. Lord. 1941. Dissert., Illinois.

214. Sandholzer *et al.* 1941. J. Bact. 41, 98.

215. Amer. Pub. Health Assoc. Year Book, 1941-1942, 158.

different depths if there is any indication of variations in salinity or pollution due to stratification. The samples should be collected in sterile bottles and should be fully protected against contamination both during sampling and after collection. They should be kept at a temperature at or below 10°C.(50°F.) and should be examined as soon as possible after collection. Every sample should preferably be tested within 12 hours from the time of collection and in no case should samples which have been held for more than 30 hours be tested.

Field Record—A record of environmental conditions made at the time of collection of the sample should accompany all water samples collected during the course of a survey to establish the sanitary condition of shellfish-growing waters. This record should include the following essential information:

- (a) Date and hour of collection.
- (b) Exact location of the sampling station.

Where possible the following supplementary data should be obtained in order to interpret the bacteriological findings:

- (a) State of the tide.
- (b) Direction and velocity of currents.
- (c) Direction and velocity of wind.
- (d) Temperature and density of the water.
- (e) Depth of the water and depth at which the sample was collected.
- (f) Temperature of the air.
- (g) Notes on any unusual conditions which may affect the sanitary quality of the water.
- (h) Record of rainfall in the immediate past.

A suitable form to be used for reporting this information may be found in the Appendix.^{215a}

Procedure—Examinations for bacteria of the coliform group shall be made by primary inoculation into plain lactose broth (see Appendix) with incubation at 37°C. (98.6°F.). After incubation for not more than 48 hours definite gas formation shall be recognized by the presence of visible gas in the upper end of the inverted fermentation tube or by the presence of effervescent gas bubbles visible only when the tube is shaken.

1. Inoculate—

- (i) Not less than three tubes with 10 ml. of undiluted water.
 - (ii) Not less than three tubes with one ml. of undiluted water.
 - (iii) Not less than three tubes with one ml. of a 1-in-10 dilution of water.
- (These dilutions may be altered to suit the degree of contamination of the water.)

Incubate tubes for 18 to 24 hours. Observe gas formation in each tube.

(a) *Gas Present*—Any amount of definite gas constitutes presumptive evidence of the presence of coliform bacteria and must be confirmed as described in step 2 below.

(b) Incubate negative tubes an additional 24 hours, making a total of 48 hours' incubation. Observe gas formation.

(i) Gas present in any amount constitutes a doubtful test which must always be confirmed (step 2).

(ii) Absence of any gas after 48 hours of incubation constitutes a final negative test.

CONFIRMATION—A. Coliform Group. All positive gas tubes must be confirmed for bacteria of the coliform group.

2. Transfer a loopful (three mm. diameter loop) of culture from the positive primary lactose broth fermentation tube to one of brilliant green bile lactose broth (see Appendix).

(a) Any amount of definite gas formation within 48 hours at 37°C. constitutes a positive test for bacteria of the coliform group.

(b) Absence of gas after 48 hours' incubation constitutes a negative test for bacteria of the coliform group.

215a. This will not be reproduced in this book but is available in the original publication.

B. *Escherichia coli**Method I.*

3. Inoculate E.M.B. plates (see Appendix) from positive lactose broth tubes which have gas present. Incubate at 37°C. for 24 hours.

4. Inoculate tubes of Koser's citrate medium (see Appendix) with a bacteriological needle from several colonies suggestive of *Escherichia coli*. The greatest care should always be exercised to secure apparently pure cultures by using only well-isolated colonies. Only a trace of the colony should be transferred, otherwise too much nutrient material may be provided. Incubate at 37°C.

Absence of growth after 24 hours constitutes a positive test for *Escherichia coli*.

Method II.

5. Inoculate tubes of modified Eijkman lactose medium (see Appendix) with a loopful of culture from primary lactose broth tubes which have gas present. Incubate at 45.5°C.

Any amount of definite gas formation within 48 hours constitutes a positive test for *Escherichia coli*.

Method III.

6. Complete all tests for *Escherichia coli* according to the recommended procedures in the Appendix to *Standard Methods of Water Analysis*.

SHELLFISH

Collection and Transportation of Sample—In general, ten or more oysters, clams, or mussels judged to be representative of the lot and of the average size of the lot under examination, with deep bowls, short unbroken lips and shells tightly closed, shall be selected and prepared for transportation to the laboratory.

Not less than one-half pint of shucked shellfish shall be collected for examination.

Shellfish selected as samples should be placed in a suitable sterilized container (such as a can with watertight lid or canvas bag) which shall be marked for identification. This same mark shall be placed in its proper place on the descriptive form which accompanies the sample. All shellfish for bacteriological examination shall be handled aseptically.

Shellfish samples should be kept at or below 10°C. (50°F.) until examined, but under no condition should they be permitted to come in direct contact with ice.

A sample shall be considered unsatisfactory which has been improperly handled after collection. Samples of shell oysters should preferably be tested within 12 hours from the time of collection and in no case should samples which have been held for more than 20 hours be tested. Samples of shucked oysters should be handled with special care and should, if at all possible, be analyzed within four hours after collection.

Field Record—A record of environmental conditions made at the time of collection of the sample should accompany all shellfish samples taken directly from growing waters. The record should include the following essential information:

(A) Exact location and depth from which they were collected.

(B) Date and hour of collection.

Where possible the following supplementary data should be obtained:

(a) State of tide.

(b) Temperature.

(c) Density of the water.

(d) Whether there has been heavy, moderate, or very little rain during or immediately preceding the period of collection.

(e) Careful notes on any unusual sources of pollution, such as boats, privies, sewers, pasture lands, animals, etc., which might affect bacteriological results.

When samples are collected from packing plants or from the market, records shall be made of:

(a) Date and hour of collection.

(b) Name and address of the place from which the samples were collected.

- (c) Exact location of the water in which the shellfish were dug.
 - (d) Identification of the digger, shipper, and reshipper, and the respective dates on which these transactions took place.
 - (e) Conditions of storage prior to collection of the sample.
 - (f) Sanitary conditions in the packing plant.
 - (g) Temperature at which shellfish were being held.
- Forms to be used for submission of these data may be found in the Appendix.²¹⁷²

Procedure—(A) Preparation of Sample for Examination.

1. *Unopened Shellfish*—(a) Scrape off excessive growth and loose material from the shellfish and scrub with a stiff brush in running water of known purity until shells are clean and free of all mud, especially in crevices at junction of shells.

The hands of the examiner should be thoroughly washed with soap and water and the brush used for scrubbing the shells should be sterilized by boiling or autoclaving.

(b) Either (1) immerse the scrubbed shellfish for 15 minutes in chlorinated water which will contain not less than 10 p.p.m. free chlorine at the end of treatment as determined by the orthotolidine test and watch the shellfish during treatment and discard any which open and cause bubbling; or (2) rinse in water free of chlorine and of known purity and place on clean paper towels and dry in the air.

(c) Open the shellfish with an oyster knife or other suitable instrument which has been sterilized by flaming or immersion for three minutes in boiling water. The point of the oyster knife can be inserted between the shells after some experience or a small opening can be made with nibbling forceps. Cut the adductor muscle of the upper flat shell if examining oysters and pry the shells apart just wide enough to drain off the shell liquor.

(d) Drain off the shell liquor into a sterile bottle, then lay the oyster on a clean paper towel and pry the shell loose at the hinge. By holding the lower (deep bowl) shell down with the oyster knife and using the knife at the same time as a lever to pry open the upper shell, the anterior edge may be grasped with the left hand and removed with the minimum chance of contamination. The removal of the shell is the most difficult part of the procedure and calls for careful technique to avoid shell liquor running on the handle and contamination of the shellfish.

(e) Cut the body of the shellfish into approximately 10 equal pieces with scissors or oyster knife, previously sterilized by autoclaving, flaming, or immersion in boiling water for three minutes, and empty into the bottle containing the shell liquor. This bottle should be a heavy-walled glass or rubber-stoppered bottle graduated at 200 ml. and 400 ml. Not less than 200 ml. of shellfish with the shell liquor should be tested, but, in no case, should less than six shellfish constitute the sample.

(f) Add about a tablespoonful of a sterile 5-mm. imperforate glass beads to the sample and shake vigorously 50 times, each shake being an up and down excursion of about a foot, time interval not exceeding 30 seconds.

(g) To 200 ml. of this well-mixed sample, add 200 ml. of sterile distilled water. Shake vigorously to mix the sample.

Allow the sample to settle for two minutes.

2. *Shellfish Removed from the Shell*—The examination of shucked shellfish shall be made in an analogous manner to that for shell stock, that is, 200 ml. of the sample (both shellfish and liquor) shall be added to 200 ml. of sterile distilled water after the bodies of the shellfish have been cut up as in step (e) above.

(B) Examination for Members of the Coliform Group and *Escherichia coli*

Examination of shellfish shall be made in a manner similar to that used for the examination of shellfish water samples.

1. Presumptive Test.

Using plain lactose broth fermentation tubes, inoculate—

(a) Each 5 tubes with 2 ml. (1 ml. of composite shellfish sample) from sample as prepared under Section A.

(b) Each of 5 tubes with 1 ml. from a 1-in-10 dilution of the composite sample (2 ml. prepared Sample A plus 8 ml. of sterile distilled water); and

(c) Each of 5 tubes with 1 ml. from a 1-in-100 dilution of the composite shellfish sample (1 ml. of 1-in-10 dilution plus 9 ml. of sterile distilled water).

If desired, further decimal dilutions may be carried out. Incubate at 37°C. for a total of 48 hours. Examine after 24 and 48 hours for the presence of gas in the tubes.

The presence of gas in any amount, or the appearance of effervescent gas on shaking a tube, shall constitute a positive presumptive test; the absence of gas, a negative presumptive test.

2. Confirmation.

A. *Coliform Group*—All positive tubes may be confirmed for bacteria of the coliform group, as described under Section 2, in the procedure for the examination of shellfish waters, by transfer to brilliant green lactose bile broth.

B. *Escherichia coli*—Confirmation for *Escherichia coli* shall be made by either of the two methods described under Sections 3, 4, and 5 in the procedure for the examination of shellfish waters, that is, either by transfer from the primary lactose broth tubes to E.M.B. plates and further identification in Koser's citrate medium or by transfer to Eijkman lactose medium at 45.5°C.

Any laboratory charged with the responsibility of examining samples of shellfish other than those known to have been freshly taken directly from growing areas would be well advised to complete all tests for *Escherichia coli* according to the procedure recommended in the Appendix to *Standard Methods of Water Analysis*. Such examinations may become the basis of legal action and short cuts are not recommended.

(C) *Colony Counts*—A standard colony count of shellfish samples has been found to be of value as an index of general sanitation and refrigeration.

Colony counts shall be made by inoculating various amounts of sample, as prepared under (A) above, into tryptone-glucose-extract-agar (see Appendix) and incubating plates at 37°C. for 48 hours.

The method of preparing plates and making the counts shall be that recommended by the American Public Health Association as a standard method for the examination of dairy products except that milk shall not be added to the medium (*Standard Methods for the Examination of Dairy Products*, Seventh Edition, 1939).

EXPRESSION OF RESULTS

The number of bacteria of the coliform group shall be expressed as the Most Probable Numbers (M.P.N.) per 100 ml. of sample. The M.P.N. shall be determined by the tables of Hoskins in Public Health Reports 49 (1934), 393-405.

The Eijkmann Test for Coliform Bacteria in Oysters. This test has received much study in water analysis, the literature of which is reviewed in Chapter 4. Perry and Hajna²¹⁶ considered it a valuable procedure when a modified Eijkman medium was used with incubation at 46°C. (114.8°F.). They believed that types other than *Escherichia coli* were eliminated. Payne²¹⁷ compared the method with other standard procedures and reported discrepancies. Standard lactose broth was observed to be more sensitive for isolating *Escherichia coli*. Hajna and Perry²¹⁸ later reported further evidence for using higher temperatures for isolating *Escherichia coli*. They reported that McConkey's lactose bile was less selective than their medium.

Hunter and Linden²¹⁹ attempted to determine whether H-ion concentration could be used to measure the bacterial count and condition of

216. Perry and Hajna. 1935. Amer. J. Pub. Health 25, 720-724.

217. Payne. 1938. Pub. Health Rpts. 53, 2058-2064.

218. Hajna and Perry. 1939. J. Bact. 38, 275-283.

219. Hunter and Linden. 1923. J. Agr. Res. 30, 971-976.

spoiled oysters. A somewhat definite relation existed between the H-ion concentration of the oyster liquor and the odor and general appearance of the oysters. When once tested, the H-ion concentration increased with the progress of spoilage regardless of the temperature or bacterial count. A pH of 5.6 to 6.1 was the critical zone where the oysters were passing from fresh to stale, while from 4.9 to 5.3 the oyster was passing from stale to sour or putrid. Total aerobic counts on oyster liquor did not correlate with physical condition and H-ion concentration of decomposing oysters. Good oysters contained as many as 30,000,000 bacteria per ml., while one often had as few as 12,000 per ml.

Sanitary Condition of Market Oysters. Oysters are indeed perishable products which require adequate refrigeration to prevent deterioration. Most investigations of a bacteriological nature have concerned determination of presence of *Escherichia coli* as an indicator of pollution and not so much the number of bacteria which may be present. The latter does not seem to have justified itself as a matter of importance mainly because the plate count is so high. Especially is this true for bulk oysters shipped to inland communities under indifferent conditions of refrigeration. Lord ²¹³ observed large numbers of *Escherichia coli* in such samples, some of which contained as many as 25,000,000 per 100 grams of oysters. Aerobic plate counts were very high, in one case being 63 below per 100 grams of sour oysters at 20°C.(68°F.).

In sharp contrast were frozen oysters. Examination of 15 samples of frozen shucked oysters revealed an almost sterile product with few *Escherichia coli*, the largest number of the latter organism observed being 80 per 100 grams of oysters. The highest aerobic plate count observed was 28,000 per 100 grams, the average being 710 colonies per 100 grams.

Mussels. These marine mollusks are widely used by people in certain sections of the country. While they may probably cause infections when they come from polluted water, they are better known as the agents for an acute toxemia which they cause at certain times of the year. The California State Department of Health finds it necessary to issue warnings of danger from eating mussels harvested on the coast of that state. Mussels are of interest to food-control officials from the fact that they may harbor pathogenic bacteria, such as *Eberthella typhosa*, and cause "mussel poisoning." Dodgson ²²⁰ published a long treatise on mussel purification. On account of the length and importance of this publication, a little more space may be given to it. A survey of causes and extent of pollution of the chief mussel beds of England and of possible preventive measures showed that chlorination of sewage is impracticable owing to lack of treatment and to many sewer outlets. Dodgson said that relief rested in treatment of mussels by cooking, relaying on non-contaminated beds, or purification in tanks. Cooking cannot be controlled and may be insufficient. Experiments, however, showed that when mussels were placed in cold water and heated to boiling for three minutes, they are safe. Relaying in tanks may fail because of lack of suitable areas and lack of co-operation. Dodg-

220. Dodgson. 1928. Gt. Brit. Min. Agr. and Fisheries, Invest., Ser. 2, 10, 1-498.

son believed that purification in tanks was the only safe method; this was also believed to be superior to a bacteriological standard. The latter were believed to be influenced by too many factors to make them reliable.

Purification of Mussels. This is advisable for most mussels. It is accomplished in different ways. Dodgson did not put much faith in relaying in clean water. Suitable areas might not be available and there might be little co-operation. Furthermore, questions might arise with respect to what waters were sufficiently clean. Dodgson reported bleaching powder to be most satisfactory for sterilizing mussels. They failed to open and function in presence of five p.p.m. of available chlorine. A mussel may open its shell and void mucus strings ("Pseudo-feces") without siphoning. These mucus strings were said to contain the bacteria, the water becoming sterile. The anatomical and physiological characteristics concerned in purification discussed by Dodgson will not be reviewed here. In 1936, Dodgson²²¹ outlined with a little more detail methods used in England for mussel purification. His discussion is especially interesting because it represents British experience. That gross and constantly increasing sewage pollution of oyster beds much be expected, is a foregone conclusion. Dodgson believes that the only solution of the problem is a satisfactory purification system. Unless such a system is workable, molluscan shellfish as a whole will have to be banned. Any system of purification will have to be reliable, relatively simple, and efficient as far as cost is concerned. The Ministry of Agriculture and Fisheries mussel purification system at Conway was described as follows:

Mussel Purification (Conway System)

The installations consist of four reinforced concrete tanks.

No. 1. Storage Tank.—Capacity 90,000 gallons. Estuarine water is pumped into this tank at or about high water and stored until required. (This storage tank is unnecessary in places where sufficient water of the right salinity can be obtained on one side.)

No. 2. Chlorinating Tank.—Capacity similar to No. 1, from which it can be filled in about 20 minutes (by gravity or by pumping).

Nos. 3 and 4. Mussel Purification Tanks.—Capacity, each, 40,000 gallons. The floors are sloping, and divided into parallel channels by concrete ridges which support wooden (pitch pine) grids. By a system of penstocks or sluices the under-grid channels can be flushed out. The mean depth of these tanks is three feet. The capacity of each tank is six tons, or about 150,000 mussels.

A solution of bleaching-powder is added to the polluted water as it enters the chlorinating tank, in quantity sufficient to give a concentration of active chlorine of three parts per million. The water is allowed to stand over one night, when sterilization is complete.

Steps in the Purification Process

I.—The polluted mussels are spread, about two deep, on the grids.

II.—The mussels are hosed with a jet of water (about 130 lb. per square inch pressure) which removes adherent mud, weed, etc., from the shells, and washes it through the grids into the sloping channels which are flushed by water from the penstock sluices.

III.—The tanks are filled with sterile sea water from the chlorinating tank. To the in-coming water is added a solution of sodium thiosulphate (hyposulphite) sufficient

221. Dodgson. 1936. Brit. Med. J., July 25, 1936, 169-174; Pub. Health 50, 279-284.

to neutralize any trace of active chlorine which may remain. In this bath of sterilized chlorine-free water the mussels remain one night. Into it they discharge all foreign matter, including bacteria, from their intestines, mantle cavities, etc., in the form of fine threads or small pellets held together by mucus. These fall to the bottom, the bacteria discharged with them remaining imprisoned in the tenacious and practically insoluble mucus.

IV.—(After 24 hours). The first bath is drained off, and the mussels are again hosed, the matter discharged by the mussels (faeces, etc.) being washed through the grids and flushed away.

V.—Second bath of sterile dechlorinated water, in which the mussels remain another night. The object of this second bath is to get rid, *via* mucoid faeces and pseudo-faeces, of any bacteria discharged free into the water and re-ingested.

VI.—(Second 24 hours). Second bath drained off. Mussels hosed and channels flushed, as in "II."

VII.—Mussels covered for one hour with sterile sea water containing three parts per million active chlorine, with a view to-sterilizing the outside of the mussel shells, grids, and tank walls, to which bacteria—some of them released from faeces, etc., during hosing—may be adhering. (There is no danger of such bacteria being splashed inside the shells, because the mussels remain tightly closed. It may be emphasized that this final bath (of one hour's duration) is the only occasion on which the mussels are exposed to active chlorine.

VIII.—Shell-sterilizing bath drained off. The fishermen, after walking through a bath of 1 in 10,000 active chlorine, to sterilize their boots, enter the tanks and pack the mussels in sacks sterilized by 1 in 10,000 chlorine solution. The sacks are sealed with a safety lead bearing the date and the legend "M.A.F. Conway" (or "L.C.C. Lytham") and are dispatched to market.

The results of purification were checked bacteriologically. A bacteriological standard for purified mussels—not more than five lactose fermenters per ml. minced mussel—was finally adopted. Dodgson²²² did not favor a chemical method of purification because the shellfish refuse to open and act as filters with a consequent failure to purify.

Bacteriological Examination of Mussels. Results of bacteriological examination of shellfish are considered by some as reliable indications of sanitary quality. Few investigators, if any, have given as much attention to this problem as Dodgson.^{220, 222} In his first report he questioned the value and interpretation of results. Chance and time interval in sampling was believed to introduce wide divergence in results from the same batch of shellfish. Glucose in the shellfish may also lead to false bacteriological results. Therefore, he did not suggest a bacteriological standard but stated that an acceptable method of purification could be standardized and maintained. In his later report in 1938, Dodgson, in discussing purified mussels, stated that they easily conformed to a standard of not more than five lactose fermenters per ml. of minced shellfish incubated at 37°C. (98.6°F.) for 24 hours, and oysters were capable of a lower standard as they usually show less than two lactose fermenters per ml. Dodgson encountered some occasions when thousands of lactose fermenters were encountered. They were not *Escherichia coli* but belonged to other sections of the coliform group. Since these did not develop at 44°C. (111.2°F.) Dodgson favored adopting that temperature for incubation instead of 37°C.

222. Dodgson. 1938. Roy. Soc. Med. Proc. 31, 925-934.

Bigger's²²³ Method for Bacteriological Examination of Mussels. The principal features of this method are rejection of the shell liquor, standardization of the volume of each mussel at 25 ml. by addition of salt solution, and inoculation in duplicate of three dilutions into MacConkey's bile salt lactose broth and reporting the results as positive only when acid and gas are produced in both tubes in 24 hours at 37°C. (98.6°F.). Bigger described his procedure as follows:

METHOD OF EXAMINATION

- (1) Ten mussels of average size are selected.
- (2) These are washed with running tap water, using a boiled nail brush.
- (3) One (A) is grasped with a sterile ovum forceps, rinsed under the tap, and then with sterile water.
- (4) It is placed on a piece of sterile parchment paper in which it is grasped with the left hand. The shell is held with the flat edge towards the body, the anterior (pointed) end to the left, and the left valve of the shell upwards.
- (5) A small portion of the shell at the broad (posterior) end is nibbled away with a sterile nibbling forceps and, through the opening, the blade of a sterile scalpel is inserted. With this the posterior adductor muscle and the other attachments of the mussel to the left valve are cut and, holding them with the paper interposed between them and the hands, the two valves of the shell are separated and the left one removed.
- (6) All the fluid in the shell is poured off and, with the help of the scalpel, the body is transferred to a small beaker provided with a graduation at the 25 c.c. level.
- (7) The body of the mussel in the beaker is thoroughly minced with a sterile pair of scissors. Sterile saline is added up to the 25 c.c. mark, and mixed thoroughly with the minced body, the scissors being used for this purpose. This is the reconstituted mussel (R.M.).
- (8) The whole contents of the beaker are transferred to a larger sterile beaker, and 25 c.c. of sterile saline are added. This is a 1/2 dilution of R.M.
- (9) With a sterile 1 c.c. pipette, 1 c.c. of 1/2 R.M. is added, after mixing with the pipette, to each of two tubes of lactose bile broth (L.B.B.). These are labeled respectively A/.5/1 and A/.5/2.
- (10) With the same pipette, 2 c.c. of 1/2 R.M. are added to 8 c.c. of sterile saline in a test-tube, making a 1/10 dilution of R.M.
- (11) With a fresh sterile 1 c.c. pipette, 1 c.c. of 1/10 R.M. is added to each of two tubes of L.B.B. These are labeled respectively A/.1/1 and A/.1/2.
- (12) With the same pipette 0.2 c.c. of 1/10 R.M. is added to each of two tubes of L.B.B. These are labelled respectively A/.02/1 and A/.02/2.
- (13) Operations 3-11 are repeated with the next mussel (B), the cultures being labelled B/.5/1, B/.5/2, B/.1/1, B/.1/2, B/.02/1, and B/.02/2. The same procedure is carried out with the other eight mussels C to J.
- (14) The cultures are incubated at 37°F. for 24 hours when the results are read (In the investigation here described an additional reading was made after a further 24 hours' incubation.)

NOTES ON METHOD OF EXAMINATION

- (1) In practice it is more convenient to complete steps 3-8 for the ten mussels before steps 9-13 are commenced.
- (2) Steps 6-8 may be condensed by transferring the body of the mussel directly from the shell to the large beaker, mincing in it, and making up the volume with sterile saline to 50 c.c.
- (3) The instruments are sterilized by boiling in a pie dish over a Bunsen burner. After a few minutes they are transferred with a flamed forceps to another pie dish containing cold sterile water in order to cool them. From this they are removed for use with flamed forceps.
- (4) The L.B.B. used is prepared in the usual way, and contains 2 per cent of peptone, 0.5 per cent of sodium taurocholate, 1 per cent of lactose and 1 per cent of Andrade's indicator. So that as much gas as possible may be collected the inner tube

almost fills the bore of the outer. It is kept in position high up in the outer tube by a dimple in the wall of the latter, made by heating a small area of the glass with a blow-pipe flame and pushing in the softened portion with a carbon rod. This device, which was suggested by my laboratory attendant, Mr. W. Kampff, is superior to the usual one of supporting the inner tube on a piece of glass rod.

To avoid the error observed by Dodgson (1928), the production of acid in the medium due to fermentation of glucose derived from the mussel body, a large volume of L.B.B. should be used in each tube. For the tubes containing 0.5 c.c. of R.M., 30 c.c. of medium are used, and 15 c.c. for the tubes containing 0.1 c.c. and 0.02 c.c. of R.M. With these amounts of L.B.B. sufficient acid cannot be produced from the glucose present in the mussel to alter the color of the indicator to red.

(5) One of the innovations requiring mention is the rejection of the shell fluid. This step, which was recommended by the Middleburg Conference, was adopted for two reasons. The first is that this fluid is little more than a sample of the last water in which the mussel opened and is, therefore, little indication of the bacterial content of the mussel body. The second is that its volume is very variable. In freshly examined mussels a large amount may be present. How much of this is included in the sample cultivated depends largely on the operator's skill. It is practically impossible to open a mussel without losing some of the fluid, especially when a fat mussel is present in a shell with a large amount of fluid. The usual procedure of mincing the body in the shell is impossible without allowing some fluid to overflow. In mussels which have been, for some days, out of water little or no shell fluid may be present. Under these circumstances it is impossible to measure a volume of minced body with a graduated pipette unless fluid, such as saline, is added. This is commonly done, but the amount added is not standardized in any way, and such addition introduces a factor of uncertainty. For these reasons it was decided to discard shell fluid, and to replace it by sterile saline.

(6) In the method used by Prof. Eyre (1924) 0.1 c.c. of mussel mince (composed of body plus a variable amount of shell fluid) is the quantity tested. This bears no constant relationship to the volume of the shell contents, and therefore the results obtained cannot be translated into number of *B. coli* per mussel. In the method here described, the reconstituted mussel has a constant volume of 25 c.c., and results obtained by cultivating from various volumes can be reported in terms of bacteria per mussel.

The body volume of an average mussel is about 15 c.c., and 20 c.c. is very rarely attained. The mixture of minced body and saline up to 25 c.c. is generally capable of being manipulated with a pipette. Where the body volume is very large, however, it will be found more convenient to transfer the body to the large beaker, and to make up the volume to 50 c.c. with saline, so giving directly at 1/2 dilution of R.M.

(7) The method of mincing the whole body, in preference to Dodgson's method (1928) of opening the alimentary tract by scraping away part of the body and "stroking" the gills, was adopted, as it was hoped to devise a method which might be used successfully by any bacteriologist called upon to examine shellfish. Dodgson's method requires more knowledge of the anatomy of the mussel than is likely to be possessed by many bacteriologists, and also a considerable amount of skill and experience.

Lobsters. This product was probably packed first at Eastport, Maine, in 1840. A poor product was secured, but arrival of Scotch canners caused improvement. The industry then spread to Canada, where it took on considerable importance. According to Harrison and Hood,²²⁴ from the beginning there was considerable spoilage of a variety known as smut, blackening, or discoloration. Prescott and Underwood²²⁵ seemed to have done some of the pioneer work on spoilage of canned lobster. They established the relation of living bacteria to spoilage. Sound cans were found to be sterile, a conclusion which is probably not in accord with present-day

224. Harrison and Hood. 1923. Roy. Soc. Canada, Proc. and Trans. 17, 145-189.

225. Prescott and Underwood. 1897. Tech. Quart. 10, 183.

ideas about sterility of canned foods. Prescott and Underwood isolated nine species of bacteria which were fully characterized. When the bacteria were put back into sterile cans and the cans processed as in the original manner, spoilage occurred in the majority of cases. Experiments showed, as would be expected, that the bacteria were heat resistant and that they could survive certain processes. Four organisms were isolated by MacPhail²²⁶ from canned lobster. They were facultative with respect to oxygen and formed gas. One was a sporeformer.

Harrison and Hood sent out a long questionnaire to all licensed canners. This information, while of indirect bacteriological interest, furnished these workers with the proper background for an intensive study of this problem. The terms smut, blackening, or discoloration were applied to either the container or its contents. Harrison and Hood reported the following changes from the normal:

1. Inky black discoloration of the meat.
2. Inky black discoloration of the can interior.
3. Bluing of the meat.
4. Brown incrustation of the can interior.
5. Brown discoloration of the paper.
6. Black discoloration of the paper.
7. Dull yellowish-white appearance of the meat.
8. Varied, other than blackening or browning; due to bacterial decomposition, manifested in many ways as general decomposition resulting in a greenish yellowish discoloration of parts of the lobster meat and alteration of the pickle producing turbidity without the production of color.

It will be impossible to give a complete review of this valuable paper, but mention may be made of some of the points of bacteriological interest. They brought out two points which were significant from the canning standpoint. "The presence of sulphur and the different pH values for the spring and fall caught lobster, and the chemical cause of discoloration is the liberation of hydrogen sulfide from the meat and the formation of iron sulfide, a black salt." Harrison,²²⁷ with other colleagues in 1921, showed that bacteria were always present in the digestive glands and intestines of freshly caught lobster. Fifty-six cultures were obtained which fell into twenty-one types. Among these was a sporeformer which had characteristics like those of *Bacillus mesentericus*. When these organisms were grown on lobster-peptone-lead-carbonate agar, six of them blackened the medium, seven slightly blackened the surface, while four gave dark and light areas on the medium. Harrison and Hood were unable to conclude from their data, however, that bacteria were the sole cause of blackening of the lobster. Miss Newton, working under the direction of Professor Harrison, isolated a number of sporeforming bacteria from the sea, over 20 of which formed hydrogen sulfide. Thermal death time studies indicated that all of the cultures but one were killed in times much shorter than those used in processing the lobster. The situation has changed greatly since Harrison and Hood's work. An enamel (C-enamel)

226. MacPhail. 1923. Twenty-ninth Ann. Rpt., Dept. of Marine and Fish.

227. Harrison.

developed since then has almost completely conquered black in canned lobster. It is very probable also that bacteria play a less significant role than Harrison and Hood believed.

CRAB MEAT

Although crabs have not had as large a place in the American diet as other shellfish, they are growing in popularity. They are probably subject to the same kind and degree of pollution to which other shellfish are subject. Need for improvement in the sanitary conditions of production, handling, and distribution of fish and shellfish throughout the United States was indicated in a committee report presented to the American Public Health Association in October, 1932.²²⁸ Hunter, who was chairman of this committee, later reviewed in the *Fishing Gazette* the practices then in use as they related to the sanitary problems. He believed that crab meat was subject to dangerous contamination unless handled properly. The recommendations which he made were such as to indicate that many sources for such contamination existed in machinery and personnel. Jarvis²²⁹ described the Alaska and Japan crab-packing industries but gave little or no information on bacteriological problems.

Purification of Crabs. Since these are harvested in many places from water of questionable sanitary quality, some attention has been given to purification. Nickerson, Fitzgerald, and Messer²³⁰ floated contaminated blue crabs in tanks through sea water containing .5 p.p.m. of chlorine. Such treatment for 24 to 48 hours removed many of the fecal organisms but not all. These investigators, however, considered the procedure to be valuable as it reduced the boiling time for both crabs and lobsters.

Fresh Crab Meat. This has been a product of considerable importance from the viewpoints of sanitation and keeping quality. Owing to the fact that it may become grossly contaminated during pickling, and to the fact that it received no special treatment for coping with the bacteria which it contains, other than storing at low temperatures or freezing, it has generally been regarded with suspicion by food-control officials. Hunter²³¹ has reviewed these problems which involved cleanliness of plant equipment as well as the more serious matter of personal cleanliness of the employees. The latter problem is more serious because of the fact that the meat must be picked from the crawfish by hand and packed by hand. Numerous samples of fresh, iced crab meat were examined by Tobin and McCleskey²³² for total bacteria count and presence of *Escherichia coli*. Many of the samples were positive for *Escherichia coli*, the most probable numbers exceeding one in 63 per cent of the samples and 10 in 20 per cent. The plate count varies from 87,000 to 16,000,000 per gram. *Escherichia coli* was found to originate largely from hands of workers, ice, and dipping brines. Partial sterilization of crab meat in an autoclave for 15 minutes

at 121°C. (249°F.) resulted in a 99.9 per cent reduction of the total bacteria and elimination of *Escherichia coli*. Tobin and McCleskey believed that the use of *Escherichia coli* as an indicator of pollution and undesirable practices was justified.

According to Harris²³³ decomposition of fresh crab meat is a progressive proteolysis, accompanied by a rapid and continuous rise in ammonia content and a more or less irregular rise in alkaline reactions; it is not due to sporebearing anaerobes but primarily to the action of the *Proteus* group, possibly supplemented by some of the *Pseudomonas* and *Flavobacterium* groups. Other bacteria isolated belonged to the *Escherichia*, *Zopfius*, *Alcaligenes*, *Achromobacter*, *Micrococcus*, *Sarcina*, and *Streptococcus* genera. There was no relation (or no close relation) between "age" of decomposition and total aerobic counts or pH. *Escherichia coli* score was high in samples spoiling at room temperature and low in samples spoiling at icebox temperature. Maximum total aerobic count was reached at room temperature the first to fourth days and at icebox temperature the 15th to 20th days; at both temperatures there was a sudden initial rise in bacterial count. The Nessler ammonia test is tentatively proposed for differentiating fresh from spoiled crab meat, before macroscopic signs of spoilage appear.

Canned Crab Meat. This now great industry in the United States has recently been described by Fellers and Harris.²³⁴ It has become an important industry in Japan since 1900 (Oshima²³⁵). The greatest problem which had to be overcome was blackening caused by formation of ferrous sulfide in the cans. It was revealed that as the difficulty increased the meat approached an alkaline reaction and came almost directly with staleness of material. The trouble was corrected by use of double-lacquered cans and strictly fresh crab meat with buffer solutions to raise the pH. Oshima recommended tartrates, citrates, or a citrate and phosphate mixture to be placed in the can. von Bonde and Marchand²³⁶ also emphasized the necessity for careful methods of packing. The crawfish were kept alive in floater crates until ready for use, graded for size and condition, prepared rapidly for canning, not too tightly packed in lacquered cans or glass jars, thoroughly exhausted, and given a short cook with prompt cooling.

Fellers and Harris²³⁴ described a new method for canning the flesh of the blue crab. The main difficulties have always been serious color and flavor changes in the canned meat resulting from decomposition of unstable proteins. The large amounts of copper have united with ammonia to form blue copper-ammonia compounds which are objectionable. Such reactions have been eliminated by dipping the crab meat into brine containing a trace of aluminum or zinc salts to stabilize the copper.

Fresh crab meat packed in one-pound, snap-lock cans and stored at 1 to 5°C. (33.8 to 41°F.) was examined by Tobin, Alford, and McCleskey²³⁷

at intervals until spoilage occurred. Changes in the total bacterial count, in the predominating species, and in the pH were determined on a large number of samples.

The initial counts varied from about 100,000 to 3,000,000 per gram. When the cans were first put into storage, the flora consisted almost exclusively of cocci, but species of *Bacillus*, *Achromobacter*, *Flavobacterium*, *Alcaligenes*, *Aerobacter*, *Escherichia*, and *Pseudomonas* were present. The total count increased steadily during storage. After a week, gram-negative rods, chiefly *Pseudomonas* and *Achromobacter*, were most numerous. At the time of definite spoilage, after 10 to 15 days of storage, the bacterial population was usually many millions per gram and consisted almost entirely of *Pseudomonas* and *Achromobacter* species. These organisms were studied in pure culture and their growth rates at 0°C.(32°F.) and at 4 to 5°C.(39.2 to 41°F.) were determined. The cultures were found to be capable of producing typical spoilage of crab meat at the usual temperature of storage, 1 to 5°C.(33.8 to 41°F.). The pH of the fresh crab meat was usually near 7.2. It increased steadily during storage until, at the time of spoilage, it was 7.8 to 8.2.

CLAMS

Several species of clams are packed along the Atlantic Coast. Since fresh clams have been incriminated in typhoid fever outbreaks it is obvious that they are subject to the same type of contamination to which other shellfish are. In the Annual Report of the Connecticut State Board of Health for 1927, page 128, is an account of such an outbreak caused by eating raw clams. Seven or eight cases appeared in one family. These clams were dug from the Thames River not far from a sewer outlet. Methods of culture, harvesting, and packing were discussed by Reed.²³

Methods for examining clams are similar to those proposed for oysters. The nature of clams, however, makes some modifications necessary. Clams are more likely to lost water during transportation than oysters. It is, therefore, necessary to take greater precautions to separate different samples of clams from each other. In opening soft clams, it has been found that if two incisions are made through the mantle, the shell water may be poured out without opening the shell. Hard clams are more difficult to open, but if the shell is struck over the dorsal muscle with a small hammer, an opening will be formed permitting the insertion of the knife to cut the muscle.

Sometimes clams and other shellfish contain too little liquor to make all of the tests above described. This is always the case when the shells are very small. Under these conditions, the water from two or more shellfish must be taken together and tested and considered as one.

WINKLES

These are marine mollusks which are harvested in waters along shores and which, consequently, may be polluted.

Nine cases of typhoid fever were traced in London in 1929 to consumption of winkles purchased from local stall holders. These observations prompted bacteriological examination of winkles by Eyre.²³⁹ Bacteriological examination of a sample of live winkles did not reveal the presence of *Eberthella typhosa* or any similar organism. It did, however, reveal that *Escherichia coli* was present to the number of over 100 per winkle. *Bacillus proteus* and *Streptococcus fecalis* were also present in large numbers. The total number of microorganisms growing at 22°C.(71.6°F.) was 2,140,000 per winkle; at 37°C.(98.6°F.) 850,000 grew. Anaerobic bacteria were also reported to the extent of 10 per winkle. A sample of boiled winkles from the same vendor revealed the presence of *Escherichia coli* to the number of one but not 10 per winkle. Numerous *Bacillus proteus* and *Streptococcus fecalis* cells were also present. The total number of microorganisms capable of growing at 22°C. averaged 4,999 per winkle and at 37°C., 22,000. Apparently the winkles were harvested from beds subject to undesirable and potentially dangerous contamination. Boiling apparently did not render the winkles safe because they were not sterilized by that treatment.

Eyre's²³⁹ Method for Bacteriological Examination of Winkles and Similar Shellfish. The procedure is the result of extended study of winkles to determine their sanitary condition.

1. Take ten (10) winkles at random from the sample.
2. Extract each fish from its shell by means of a strong stiletto and transfer to a sterile mortar.
3. Triturate the bodies of the fish very thoroughly, adding sterile 3 per cent saline solution to a total amount of 10 c.c. to the contents of the mortar during the process. Allow the emulsion to stand for a few minutes while the debris settles. Decant the turbid supernatant fluid (O.F.) (original fluid) into a 250 c.c. Erlenmeyer flask (sterile).
- It is now assumed that the entire bacterial content from one winkle is contained in each cubic centimeter of the O.F.)
4. Use 0.1 c.c. of the original fluid (equivalent to 1/10 winkle) to inseminate three nutrose agar plates in series.
5. Prepare two surface plate cultures, each with 0.1 c.c. of the O.F. upon Wilson's iron bismuth agar for the detection of members of the typhoid group or Salmonella. Incubate these five plates at 37°C. for 48 hours.
6. Add 90 c.c. of the sterile hypertonic saline to the winkle bodies in the mortar and mix thoroughly.
7. Transfer the mixture to a sterile conical urine glass. Protect this receptacle by covering it with the half of a petri capsule, and allow it to remain undisturbed for about 10 minutes while the debris settles down. Then decant the supernatant fluid into the flask containing the remainder of the original fluid.
- It is now assumed that the bacteria contained in every quanta of 10 c.c. of this "secondary" fluid (S.F.) represent the bacteriological flora of an average winkle.

QUANTITATIVE EXAMINATION

8. Prepare decimal dilutions from 1 c.c. of the secondary fluid, thus:

(1) 1 c.c. secondary fluid	9 c.c. salt solution A
(2) 1 c.c. A	9 c.c. salt solution B
(3) 1 c.c. B	9 c.c. salt solution C
(4) 1 c.c. C	9 c.c. salt solution D

9. Prepare a series of agar plates containing, respectively, 1 c.c. of secondary fluid and 1 c.c. from each of the dilutions A, B, C, D. Incubate at 37°C. for 48 hours and then enumerate the resulting colonies.

10. Prepare precisely similar set of gelatine plates. Incubate at 22°C. for 72 hours and then enumerate the resulting colonies. This set of plates also serves for the enumeration of *B. proteus*.

11. A. *B. coli*. Prepare a set of cultures in bile salt lactose broth thus—using double strength medium in large tubes for the first two—and incubate for 24 hours

- | | | |
|-----|---|--------------------|
| (a) | 10 c.c. secondary fluid (1 winkle) | |
| (b) | 5 c.c. secondary fluid ($\frac{1}{2}$ winkle) | |
| (c) | 2 c.c. secondary fluid ($\frac{1}{5}$ winkle) | |
| (d) | 1 c.c. secondary fluid ($\frac{1}{10}$ winkle) | |
| (e) | 1 c.c. fluid from dilution A (see par. 8) | 1/100 winkle |
| (f) | 1 c.c. fluid from dilution B | 1/1000 winkle |
| (g) | 1 c.c. fluid from dilution C | 1/10,000 winkle |
| (h) | 1 c.c. fluid from dilution D | 1/100,000 winkle |
| (i) | 0.1 c.c. fluid from dilution D | 1/1,000,000 winkle |

12. *B. Streptococci*. Prepare a precisely similar set of cultures using 2 per cent glucose broth instead of bile salt broth.

13. D. *B. proteus*. For the recognition and enumeration of this organism the gelatine plates prepared as per paragraph 10 are again utilized.

14. C. Spores of *B. welchii*. Inoculate into litmus milk

- 10 c.c. secondary fluid
- 5 c.c. secondary fluid
- 2 c.c. secondary fluid
- 1 c.c. secondary fluid

Heat to 80°C. for 10 minutes in water bath and incubate anaerobically for 48 hours.

SHRIMP

Shrimp is a decapod crustacean (*Crago vulgaris*) found especially in waters about the southern states. This product is used fresh when preserved by refrigeration, and large quantities are also canned in tin and glass containers. General features of the industry have been reviewed in various places.²⁴⁰ Thorough washing at various places in preparation of the meat is necessary to remove foreign matter and spoilage microorganisms.

The shrimp industry is a continual fight with spoilage microorganisms. Most of the improvements which have been introduced into the industry have as a basis better control of them. Cameron and Williams²⁴¹ showed the importance of various steps in preparation of shrimp on the basis of its load of microorganisms. One observation is obvious from their work—the extremely large number of bacteria which are always present. This situation makes it necessary to handle the shrimp meat as quickly as possible. Cameron and Williams also mentioned the value of chlorine compounds for cleaning table surfaces and utensils.

Canned Shrimp. Quality of this product depends on prompt icing and careful handling immediately after catching. Shrimp is a very perishable food and since it is taken, as Clarke²⁴² has stated, from waters where warm weather prevails, special attention must be given to methods which will

240. Canning Age, June 1926.

prevent decomposition. Detection of decomposed fresh shrimp is comparatively easy since it undergoes changes in appearance and odor which are obvious. After canning, however, it is difficult to detect decomposition unless it is extreme. The Food and Drug Administration, by means of experimental packs of shrimp, were able to devise methods for detecting presence of decomposed shrimp in the canned article. Seizure of much canned shrimp caused the packers to impose on themselves an inspection which has brought their product to an acceptable position in the eyes of food-control officials. By 1937 about 95 per cent of shrimp production was under government inspection. Revised regulations governing packing methods to be used by shrimp canners who wish to label their product "Production supervised by the U. S. Food and Drug Administration" became effective July 1, 1937.²⁴³ These included recommendations for construction of the plant, its operation, and processes for the product in both wet and dry packs.

243. *The Canner*, June 26, 1937.

CHAPTER 21

MEAT AND MEAT PRODUCTS

Meat and meat products are of interest to food bacteriologists for various reasons. Microorganisms have important roles in curing meats, contributing to good color and flavor. They are believed to contribute to flavor of sausage and other specialties. On the other hand, they may spoil meat or even make it deleterious to health. The great meat-preservation industry is based largely on strict control of microorganisms. Every attempt is made to create conditions which will either prevent their development if they are undesirable forms or favor growth if they are desirable forms. In some cases several methods of preservation are applied to the same product.

Both chemical and bacteriological methods have been proposed for determining whether meat has become unsound. Many of them have been found to be of no value. Organoleptic tests, largely used for fresh meats and sea foods, leave much to be desired. Fellers (Chairman)¹ pointed out the difficulties of determining when meats are spoiled. Detection of incipient spoilage is the difficult problem. Those who wish a short review of suggested methods should read the committee report by Fellers. Significance of hydrogen-ion concentration in food spoilage, in general, has prompted some to suggest that changes in fresh meats might mean spoilage. Schmidt² stated that a reaction, more alkaline than pH 6.3, indicated incipient putrefaction. When meat was inoculated with pure cultures of bacteria which might be expected in such a product, its reaction was rendered more alkaline. Herzner and Mann³ stated that a reaction of pH 6.0 to 6.2 indicated incipient spoilage, a value not different from that proposed by Schmidt. It is doubtful whether pH methods can be used for determining the fitness of meat. The pH of meat depends on too many variable factors, such as autolysis, rapidity of chilling, etc. Furthermore, for some people, changes which would alter the pH significantly would be considered desirable. For these reasons, slight changes in pH could not be the only methods for judging the quality of meat. This may not be true for all meat products.

Bacteriological Methods. Even though microorganisms are involved in meat spoilage, ordinary bacteriological methods have not been of much value for determining whether meats are spoiled or not. Conradi⁴ suggested an elaborate method which involved isolation of pure cultures. Zwick and Weichel⁵ also attempted to use bacteriological methods for detecting undesirable meat. Weaver⁶ tried to devise a method based on

1. Fellers. 1929. *Amer. J. Pub. Health* 19, 389-392.

2. Schmidt. 1928. *Arch. f. Hyg.* 100, 377-392.

3. Herzner and Mann. 1926. *Ztschr. f. Untersuch. der Lebensmtl.* 52, 215-242.

4. Conradi. 1909. *Zeit. f. Fleisch u. Michyg.* 19, 341-345.

5. Zwick and Weichel. 1911. *Arb. K. Gsndhtsamt.* 38, 327-337.

6. Weaver. 1927. *Mich. Agr. Expt. Sta. Tech. Bull.* 79, 28.

the appearance of indole-producing bacteria. A hydrogen-sulfide method was also suggested. Schellhorn⁷ even proposed a mouse-feeding test. It would be cumbrous for routine work, as Berg⁸ stated. Before such methods could be used for detecting unsound meat, much work would have to be done with them on meat from healthy animals. Bacteriological methods probably have distinct limitations in routine meat examination on account of the time consumed and the fact that meat may acquire many bacteria after preparation for the market.

Comparative chemical and bacteriological observations by Wright⁹ on fresh and frozen New Zealand lamb, indicated little difference so far as bacterial content was concerned. The surface was infected with bacteria, but the interior remained sterile. It was found by experiment that when kept at a temperature of 15.5 to 25°C. (60 to 77°F.) the surface bacteria could invade the interior of the lamb in five days and the interior of the mutton in seven days, but no bacterial growth or invasion took place at a temperature of —16.7 to —7.2°C. (2 to 19°F.). An extensive report was made by Metzger¹⁰ on the character and extent of bacterial infection in flesh of animals condemned as diseased, but which, under certain restrictions, could be slaughtered and sold in Germany for human food. He believed that by microscope inspection alone, a larger proportion of meat than is necessary may be kept from sale; for this reason it was suggested that more information be sought so that the industry would not suffer. Some have suggested bacteriological examinations with plate cultures which would reveal not only numbers but types as well. Such a practice has not been followed as much in America as on the continent. Pohl,¹¹ for instance, was able to show presence of *Salmonella enteritidis* in many samples of meat. Haines¹² reviewed the various problems of meat preservation and the microorganisms involved.

Meat Inspection. Attempts to protect the public health by preventing sale of meat from diseased animals have caused federal and state health authorities to establish a comprehensive organization for this purpose. The Bureau of Animal Industry is empowered with these duties for meat and meat products to be sold in interstate traffic in the United States. Meat inspection has been practiced since the earliest times. Moses gave specific instructions. In early days, meat inspection, according to Müller,¹³ was related to religious rites and ceremonies, and had nothing to do with preventive medicine. When the science of morbid anatomy became sufficiently developed, meat inspection began to follow the principles laid down by pathologists. According to Wieser,¹⁴ all meat destined for human consumption should be inspected. He collected details of 20 outbreaks of

14. Wieser. 1930. Ztschr. f. Hyg. u. Infektionskrank 10, 333-355.

food poisoning, traced to ingestion of meat preserved by pickling or smoking. Meat inspection is chiefly concerned with the following diseases: anthrax, actinomycosis, caseous lymphadenitis, foot-and-mouth disease, tuberculosis, and a few of the parasitic diseases (*Cyticercus bovis*, *C. cellulosus*, and *Trichinella spiralis*) (Grant¹⁵). Routine inspection not only protects the consumer but also gives valuable information on the distribution of animal diseases. The meat inspection service rendered by the United States Veterinary Corps is, according to Dildine,¹⁶ more extended, for the product is controlled until it is prepared for the table.

Federal Inspection. In the United States, the Department of Agriculture is empowered to inspect meat sold in interstate traffic. The inspection begins even before the live animals are driven to slaughter. If an animal is observed which seems to be ill, it receives a tag marked "U. S. Condemned" or "U. S. Suspect." When the animal is condemned, it cannot be taken into the slaughter room. Suspected animals are slaughtered separately from other animals. This is ante-mortem inspection. Post-mortem inspection involves careful examination of every part of the carcass. According to Mohler,¹⁷ government inspectors, trained veterinarians, start inspection in the case of beef when the animal is skinned. The head is cut off and several lymph glands are opened for signs of abnormality and infection. The tongue is thoroughly examined as are also the cheek muscles to insure freedom from cysts that might produce tapeworms. The viscera are examined with just as much care. These are removed from the carcass and placed before the inspector on a well-lighted table. The carcass is then inspected with equal care. Attention is given to the possibility of nodules on the ribs as signs of tuberculosis. Membranes of the chest and abdomen, the various groups of lymph glands, the kidneys, split backbone, and body generally are carefully examined. If examination of the various portions of the carcass indicates satisfactory condition, the animal is considered to be free from disease and is marked "U. S. Inspected and Passed." Each cut of meat from the carcass may then receive the same stamp of approval—the purple federal meat inspection stamp. The flesh of animals which is condemned by federal inspectors is made into fertilizers and not used for food. Such meat must be destroyed or denatured in the presence of an inspector who has to file a report. Provision is made, however, for use of the flesh of some animals which are infected with tuberculosis. If the lesions are not excessive the meat is sold as "sterilized" after all portions have been heated to 76.7°C. (170°F.) for 30 minutes.

Local Inspection. Not all meat distributed in the United States can be inspected by the Bureau of Animal Industry. Only that which is shipped in interstate traffic can be so inspected. Some meat is inspected by local agencies and much so-called "home-killed" meat is not inspected at all. This is an unfortunate situation. The Bureau of Animal Industry will act in an advisory capacity to cities which wish to institute meat

inspection. They may even stamp inspected meat, using a mark easily distinguishable from the federal stamp. Early in 1926, Chicago made a regulation that no carcass of an animal which had not been inspected by the Bureau of Animal Industry should be shipped into Chicago without the viscera attached.

Microorganisms in Blood and Tissues of Healthy Animals. Whether blood and tissues of animals which appear to be healthy contain viable microorganisms or not, is a controversial matter even though many investigations have been made. The results secured were probably influenced by the technic, media, and methods used. Maurel¹⁸ reported presence of a diplococcus. Conradi,⁴ using a special enrichment method, found 72 specimens of tissue, out of 162 pieces taken from 150 animals, to contain bacteria. The liver was most frequently infected, although bacteria were found in 18 out of 59 pieces of muscle. *Salmonella suipestifer* was found on four occasions in the muscle. Bierotti and Machilda¹⁹ also published similar results. Zwick and Weichel⁵ reported the liver of animals to be frequently infected. Hoagland *et al.*²⁰ stated that certain bacteria, chiefly micrococci, might be normally present in tissue of healthy animals slaughtered for beef. These bacteria were said to possess no pathological significance and do not appear to multiply in carcasses during cold storage. Similar conclusions were reached by Wrzosek,²¹ Rzegocinski,²² Horn,²³ Westholz,²⁴ and many others. This subject is important in the meat-preservation industry, an industry which wages a constant fight with bacteria. Reith's²⁵ work originated in an attempt to determine the flora of sound and sour hams. Cultures of the muscular tissue of slaughtered hogs showed the presence of bacteria in 77 per cent of 216 specimens; in 37 per cent anaerobes were found. Cultures of the muscular tissues of healthy live hogs, rabbits, and guinea pigs showed the presence of bacteria in 83 per cent of 108 samples; 49 per cent of the samples contained anaerobes. Cultures of the blood of healthy live hogs, rabbits, and guinea pigs showed the presence of bacteria in 84 per cent of 38 samples; 39 per cent contained anaerobes. A brief period of starvation, 36 to 48 hours, had no appreciable effect on the presence of bacteria in the tissues.

Partial identification of bacteria was attempted. Morphological identification of 96 strains gave a grouping as follows:

- 55 (59 per cent) staphylococci
- 21 (22 per cent) bipolar rods
- 18 (19 per cent) Gram-positive rods
- 15 (16 per cent) coccus forms other than staphylococci
- 6 (6 per cent) Gram-negative rods

Reith suggested that the high percentage of cocci and bipolar organisms indicated invasion from the respiratory tract and skin. Very few Gram-negative rods were found. If invasion from the intestinal tract occurred, a high percentage of *Escherichia coli* would be found; only two were reported. The isolation of anaerobic bacteria from the tissues is of importance to the meat industry. Those which were isolated were proteolytic and might produce souring of the meat unless their growth was restricted by refrigeration, pickling solutions, etc. Hoagland, McBryde, and Powick²⁰ found a small micrococcus in four out of seven carcasses of beef. The organism did not seem to be disseminated throughout the muscular tissue of any one quarter but was encountered only here and there. These authors believed that the organism was present in the tissues at the time of slaughter. It was said to have no significance and did not multiply in the tissues. Possible post-mortem invasion would generally be admitted, although if results by Burn²⁶ are representative, this would be determined by the species. *Clostridium welchii*, *Escherichia coli*, and staphylococci were the only species which successfully invaded the bodies of guinea pigs after death. Burn believed that post-mortem invasion could be a factor in accounting for bacteria within organs and body fluids.

Microorganisms on Meat. The significance of microorganisms as agents causing meat spoilage has prompted many investigations of their numbers and types. During transit under cold storage, various microorganisms may develop. Spoilage may be of various types. *Achromobacter* species of bacteria may cause sliminess and other species may cause rancidity of fat. The bacterial contamination of chilled beef largely determines its life, as Thorpe²⁷ has stated. He reported that methods of slaughtering and handling have made it possible to hold chilled beef longer. The basic reasons for this were stated by Moran²⁸ and involves sound hygienic practice of slaughtering, which results in fewer microorganisms to be controlled. Haines,²⁹ in attempts to learn the extent to which carcasses are contaminated in the slaughterhouse, found few bacteria; they were present in ice brine pipes and in sweepings from floors. He believed that bacterial contamination of carcasses in well-conducted storage warehouses was negligible. *Actinomyces* species were quite common. He also found that bacteria develop quite slowly on beef at first. During this lag period they are developing on soluble nitrogenous substances already present on the beef. After a lag period of some 40 hours at 37° (98.6°F.), they develop rapidly. Quite wide variations in bacterial count of meats were observed by Brewer.³⁰ *Escherichia coli* was abundant when counts were high. This was not related to appearance. The samples which Brewer used were cuts which would be purchased in small shops.

Brooks, Haines, Moran, and Pace,³¹ in experiments on bacon curing, found many bacteria on sides of fresh pork prepared under laboratory

conditions. For two batches of pigs, it averaged 2×10^6 and 160,000 per sq. cm. After prechilling operations it was reduced to about 400 per sq. cm.; it was further reduced during chilling to between 100 and 200. Commercial sides of pork gave a mean count after chilling of 28,000, after curing of 60,000, and after maturation of 10^6 or more organisms per square centimeter. Many bacteria were found by Jensen and Hess²²² on the skin of hogs where the jugular vein is stuck. These were significant, for among them many Clostridia were found which could be carried into the blood stream by the sticking knife. Short storage life of chilled beef has been a problem in shipping it from Australia to England. Since microorganisms are responsible for most spoilage, Empey and Scott³² studied their origin. While various factors are involved in contributing microorganisms to beef, the chief source was the hide and hair of the slaughtered animals. Two different temperatures were used, 20°C.(68°F.) and -1°C.(30.2°F.). The main contamination is bacterial, particularly at 20°C.(68°F.). At -1°C.(30.2°F.) molds and yeasts may constitute 35 per cent of the initial microbial population on beef after slaughter. At -1°C.(30.2°F.) *Achromobacter* species constituted 90 per cent of the flora. No investigation of types was made at 20°C.(68°F.). Introduction of various sanitary measures caused fewer bacteria to be present. These results were in general confirmed by Ingram.³³ To determine the effect of salt on these organisms, he mixed minced pork with salt in concentrations from 0 to 25 per cent and stored it at 0°C.(32°F.). In concentrations less than four per cent, the meat was covered by a fluid film containing *Pseudomonas* in practically a pure culture. Putrefaction occurred with a sweet odor at first. In concentrations between four and 10 per cent, the flora was dominated by molds, especially *Thamnidium chaetocladioides*. Species of *Cladosporium* and *Penicillium* also occurred. The bacterial flora consisted of yellow Micrococci and *Pseudomonas*. Above 10 per cent of salt, the flora was restricted to a few yellow micrococci quite like *Micrococcus flavescens* along with an unidentified species of *Penicillium*. This flora persisted in concentrations of salt up to 25 per cent. Spoilage of meat has been found to be due to various types of microorganisms. An organism of the *Pseudomonas fluorescens* group was found by Haines³⁴ to produce an unpleasant sour smell. Since it was found to hydrolyze fat in agar media, explanation thus exists for appearance of free acids in fat or stored carcasses. Slime on stored meat was later reported by Haines to be composed of *Achromobacter* organisms. Other defects of meat were found to be due to other species by Rolle and Pavasar.³⁵ Similar observations were made by Kolobolotsky.³⁶ *Escherichia coli* and *Bacillus proteus vulgaris* were found to be active in putrefaction.

Various factors which influence development of bacteria in cultures probably influence their development on meat surfaces. The two most

important are temperature and humidity. More is known about effects of temperature than humidity. Ewell³⁷ observed that growth of bacteria on meat surfaces ceased at relative humidities below 92 per cent and that bacteria grew with great rapidity at the highest attainable humidity of 99 per cent. He also suggested that molds might become acclimated to ozone. However, ozone was said to be useful because it decreased infection. Haines and Smith³⁸ observed some bacterial growth at a relative humidity of 70 per cent in still air. Growth was, however, in proportion to humidity.

Haines¹² Methods for Bacteriological Examination of Tissues. Two methods were devised for enumerating bacteria on tissues, the direct microscope or total count and count of viable organisms by plating on suitable media. The former can be used only when a liquid sample containing one million organisms can be obtained. Suitable dilutions of the fluid are counted in a modified hemacytometer chamber used by Wilson.³⁹ For the viable count, a series of plates are poured using suitable media. The latter method yields results which are more useful, for pure cultures may be picked and some information gained about the composition of the flora.

Since spoilage of tissues, apart from special cases of anaerobic processes, is due to growth on the surface of the carcass, the best procedure, according to Haines, is to make counts per unit of superficial tissue. His method for this was as follows: A sterile cork borer is pressed vertically into the tissues to a depth of one centimeter or more. By this means a cylinder of tissue is left, and from its top a disc about two millimeters thick is cut with sterile scalpel. The area of this disc may be computed from the diameter of the cork borer. Microorganisms on the surface of the sample may be brought into suspension by shaking vigorously with glass beads and sterile salt solution. When it is believed that bacteria may have penetrated, a thicker disc of meat may be taken and ground, or disintegrated with a mechanical stirrer and sterile sand. Haines' device for this was made with a straight-walled test tube about 15 x 2.5 cm. provided with a bent stirring rod extending through the cork. This is connected at its top to a motor. It is probable that the disintegrators used in the United States in analysis of paper board would be suitable and perhaps superior.

Gas Storage of Meat. This has been introduced in recent years to prolong storage life of meat. Ozone and carbon dioxide are the gases which have had most study. Both have been discussed in Chapter 1.

Ozone. This gas cannot be used in high concentrations because it causes rancidity and bad flavors in the fat. In low concentrations, beneficial effects in controlling microbial life have been claimed for it. Results of experiments by Haines¹² indicated that ozone may react with oxidizable substances to result in a pH of between 4 and 5. This in itself may inhibit growth of bacteria. Haines observed that high concentrations of ozone were required to arrest established growth—of the order of 1,000 p.p.m. by volume. Smaller amounts suffice if admitted with the inoculum. Haines also observed specificity of ozone for certain species while others were not affected. Experiments with lean meat in a saturated atmosphere at 0°C. (32°F.) indicated that 10 p.p.m. had little effect on slime-producing bacteria. For these reasons, ozone was believed to be of little value for inhibiting growth on meat. The amounts required cannot be tolerated by human beings and have deleterious effects on fat.

Carbon Dioxide. This gas has had a checkered reputation in food preservation. Those who favor its use believe that it increases the storage life of meat by inhibiting development of microorganisms. Those who believe to the contrary point to loss of color and flavor and even an accelerated development of certain food-poisoning bacteria. The latter is a factor which cannot be overlooked, for an atmosphere containing appreciable amounts of carbon dioxide favors development of food-poisoning staphylococci. According to Tomkins⁴⁰ presence of carbon dioxide increases the latent period of germination and decreases the rate of elongation of germ tubes of fungi on meat. The percentage germination of the species with which he worked was reduced only in concentration noticeably prolonging the latent period. Growth of colonies was retarded by carbon dioxide to a somewhat greater extent than germination. The concentration of carbon dioxide needed to prevent growth depended on temperature, the lower the temperature the smaller the amounts of carbon dioxide needed. Resistance of the different fungi to carbon dioxide varied, *Sporotrichum carnis* needing higher amounts. Tomkins observed that other factors than pH explained inhibitive action of carbon dioxide. About this same time Callow⁴¹ also reported favorable results from storing pork and bacon in carbon dioxide. Small pieces of pork were kept in perfect condition for over two months at 0°C.(32°F.) in desiccators filled with carbon dioxide. Pork stored in air spoiled in 17 days.

Since it was believed that carbon-dioxide storage might aid in transporting chilled beef from Australia to England, Empey and Vickery⁴² studied the microbial flora under conditions that would obtain in such shipments. They realized that means must be found for checking proliferation of microorganisms on superficial tissues at temperatures above the freezing point [$-1^{\circ}\text{C}.$ (30.2°F.)], for deterioration is almost wholly due to them. The low temperature bacteria found initially on the beef consisted of at least 95 per cent of types belonging to *Achromobacter*, the remainder being species of *Pseudomonas* and *Micrococcus*. In all tests counts of low-temperature molds obtained immediately after slaughter, and after completion of chilling were extremely low compared with counts of low-temperature bacteria. In one test, after 42 days' storage, no visible mold was present on beef stored in atmospheres of 10 to 12 per cent carbon dioxide, whereas beef stored in air had an average population (per area of two sq. cm.) of 10 to 60 colonies, mostly *Penicillium expansum*, though *Sporotrichum carnis* was also present. Quarters of beef stored in 12 per cent carbon dioxide even for 55 days showed only three or four colonies per quarter, all of *S. carnis*.

To restrict microbial growth on stored chilled beef the temperature should be maintained as near as possible to the freezing point of the muscle tissue, i.e., $-1^{\circ}\text{C}.$ Use of 10 to 12 per cent carbon dioxide in the storage atmosphere increased the storage life of chilled beef from meat plants

where the initial contamination consists chiefly of *Achromobacter* by 40 per cent, as compared with storage in air; effectively controlled *P. expansum* and most other meat molds, and moderately restricted the growth of *S. carnis*.

Moran⁴³ also concurred in the opinion that carbon dioxide was beneficial for storage of chilled beef. He said that in 10 to 20 per cent of carbon dioxide, beef could be kept in first-class condition for 60 to 70 days. This has made it possible for Australia to compete with South America in shipping beef to England. Carbon dioxide does not destroy fungi on beef but merely inhibits them.

Preservation of Meats by Chilling (Cold Storage) and Refrigeration. The value of prompt and adequate chilling of meat is appreciated more today than ever. Quarters or halves are placed in coolers just as soon as possible after slaughter and dressing. Before meat is subjected to other treatment, it is usually thoroughly chilled. The early years of the industry have been reviewed by Stiles.⁴⁵ In 1868, Tellier was unsuccessful in carrying meat at slightly above 0°C. (32°F.) from London to South America, but succeeded in 1876 in carrying from Rouen to Buenos Aires, 10 carcasses of beef, 12 of mutton, two calves, one pig, and 50 birds (Stiles). Results of this experimental work was probably the foundation for the great meat industry of South America which finds markets thousands of miles away. Brooks⁴⁶ stated that in 1877 the *Paraguay* sailed from Marseilles for Buenos Aires with four frozen quarters of beef and 10 frozen sheep. On the return trip, 80 tons of frozen meat were carried. The trade in frozen meat between England and Australia seems to have had its origin in 1879 when the *Strathleven* sailed from Sydney for London with 40 tons of beef and mutton.

Most meats are ripened or conditioned before distribution. They are held at low temperatures above freezing in order to allow the meat to become tender. The length of the ripening period depends on the type of product desired. Some beef is ripened for as long as six weeks at 1 to 2°C. (33.8 to 35.6°F.). Hoagland, McBryde, and Powick²⁰ published the results of observations, as did Moran and Smith.⁴⁷ Gautier⁴⁸ compared fresh meat with that frozen at -3 to -5°C. (26 to 23°F.) for five to six months. He noticed little difference, but stated that a slice of the thawed frozen meat did not keep as well in air at 12 to 18°C. (53.6 to 64.4°F.) as did fresh meat. Richardson and Scherubel⁴⁹ studied meat held at above and below freezing [-9°C. (15.8°F.)]. Frozen fresh beef was held satisfactorily for 554 days. Observations were published on meat held above zero. As time went on, perceptible changes were apparent, as were reported by Emmett and Grindley⁵⁰ and Hoagland, McBryde, and Powick.²⁰ About the same

observations were made by Wright⁹ on frozen and fresh New Zealand lamb. Moran and Smith⁴⁷ held beef for 17 days at 5°C.(41°F.) with constant improvement. Burrows⁵¹ reported observations on a quarter of beef which was kept frozen for 14 years. No evidences of putrefaction were noticeable. Fibers of the meat appeared to be normal and it was consumed with no ill effects. Even in the frozen condition, slight changes have been reported by Ascoli and Silvestri.⁵² Müller⁵³ stated that microorganisms were almost completely checked in meat and fish stored at 0°C.(32°F.). Richardson⁵⁴ believed that any unfrozen juice which existed would be too concentrated to permit bacterial growth.

Temperature of storage is another factor which greatly influences development of microorganisms on meat. According to Lea⁵⁵ beef stored at 0°C.(32°F.) for 60 days showed very little bacterial growth. Slight development of mold was observed, however. The odor of the meat was good after this storage period. Little work seems to have been carried out with pathogenic bacteria which might be present. Krüger⁵⁶ reported that flesh of slaughtered cattle may sometimes contain Bang's bacillus. He found them in three of 30 cattle. After 14 days' refrigeration the meat was still infectious for small experimental animals. de Saint Moulin⁵⁷ found *Clostridium septicum* on horse flesh carcasses. Freshly isolated strains were highly pathogenic for guinea pigs.

As a part of their extensive investigations on storage of Australian beef, Scott⁵⁸ and Scott and Vickery⁵⁹ studied the influence of temperature of storage on microbial content. Such studies are necessary for learning the best conditions for cold storage of beef and its spoilage. Growth was studied on 1.1 mm. thick slices of the *biceps femoris* muscle of the ox. Inoculation of the muscle was accomplished by spraying saline suspensions containing 5×10^6 cells. This method gave fairly uniform distribution of about 1,000 organisms per square centimeter. Slices were stored at temperatures ranging from 1°C. (33.8°F.) to 30°C.(86°F.). The meat was examined after grinding in a mortar to a uniform suspension. Plating was on agar at 20°C.(68°F.). Scott⁵⁸ believed that some bacteria are truly psychrophilic and have a low optimum temperature for growth. These would be the species which cause concern to meat packers. Scott and Vickery⁵⁹ also resorted to inoculation experiments with *Achromobacter* on sides of beef. Sharp cooling was found to inhibit development of bacteria. The moisture content of the surface of meat was also found to be a matter of considerable importance. Surface desiccation and rate of cooling of surface tissues determined extent of changes in bacterial population. The greater the rate of cooling the better was the control of bacteria. This very

interesting report should be examined by those who are working in this field. Schmidt⁶⁰ stated that the belief that meat is a favorable medium for bacteria only above the dew point is erroneous. He stated that development of bacteria varies more nearly exponentially with relative humidity; since bacteria develop well in a relative humidity of 90 to 100 per cent, this degree of humidity should be avoided in refrigerators. A temperature of $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$) in Haines'⁶¹ experiments was not sufficiently low to inhibit microbial action in frozen meats. His experiments showed that $-10^{\circ}\text{C}.$ ($14^{\circ}\text{F}.$) was satisfactory. Haines' work involved observations on the rate of growth of microorganisms on a stored carcass of lamb held at $-5^{\circ}\text{C}.$ ($23^{\circ}\text{F}.$). At first there was a decrease in numbers followed by an increase in numbers, mainly yeasts and molds. Haines' work indicated that microorganisms might also be responsible for changes in fat. Experiments in this field become quite complicated if all of the factors involved are followed. In practical storage of chilled meat some of these factors are temperature, humidity, and rates of air movement. Schwartz and Loeser⁶² did not find it possible to inhibit completely either bacterial growth or loss of weight by any combination of these factors. Results of their experiments suggested that the most effective temperature to strive for in meat storage is $0^{\circ}\text{C}.$ ($32^{\circ}\text{F}.$) with relative humidity of 90 per cent. Rates of air movement should be such as to ensure fairly uniform composition of air in all parts of the storage chamber.

"Black Spot" on Frozen Meat. As the name indicates, this is made evident by the presence of black spots after cold storage for a time. It presents an unsightly appearance, which may cause difficulties with inspectors. The British food inspectors have had this to contend with in meat imported into England from Argentina, New Zealand, and other countries.

These black spots on frozen beef were studied by Klein,⁶⁴ who attributed them to a yeast of the genus *Saccharomyces*. Animal experiments showed it to be harmless. He stated that it would grow at $-2^{\circ}\text{C}.$ ($28.4^{\circ}\text{F}.$) but not at $-9^{\circ}\text{C}.$ ($15.8^{\circ}\text{F}.$). Later, Klein⁶⁵ reported *Oidium carnis*, a fungus, as the cause, also found to be nonpathogenic by animal experiments. Klein believed that much beef from Argentina which contained black spots has been needlessly rejected, for the deeper layers of the tissue were satisfactory. The spots did not extend deeper than 1/12 to 1/16 inch.

Müller⁶⁶ and Brooks and Kidd⁶⁷ attributed black spots to *Cladosporium herbarum*. The latter observed the spoilage on lamb, veal, and rabbit. The spots consisted of mold hyphae which could be easily brushed from the meat. Brooks and Kidd stated that the fungus grew very slowly at -7.8 to $-5.6^{\circ}\text{C}.$ (18 to $22^{\circ}\text{F}.$) and produced black spots by inoculation after

six months. The fungus seemed to have little effect on the tissues. Mold flora of meat is by no means limited to the species just mentioned. While meat infected with black spot is unsightly, presence of *Cladosporium herbarum* alone does not make it unfit for use. No toxic substances are produced. If the deterioration is accompanied by putrefactive bacteria, it should be condemned.

Monvoisin⁶⁸ isolated the following species: *Thamnidium elegans*, *Mucor mucedo*, *Rhizopus nigricans*, various *Penicillia*, and *Cladosporium herbarum*. It was stated again that the molds did not seem to harm meat. Bidault⁶⁹ isolated *Cladosporium herbarum*, although it was by no means the most frequent fungus. Bidault, as did Monvoisin, believed that meat became contaminated at time of slaughter. If it is desired to entirely eliminate mold, Bidault and also Wright⁷⁰ suggested that care be used at time of slaughter to maintain sanitary conditions and that meat be stored at not higher than -9°C. (15.8°F.). Wright did not consider *Cladosporium herbarum* to be important, because it was the fungus found least frequently. On account of this statement, Brooks⁷¹ was led to repeat some of the experiments reported by Brooks and Kidd⁶⁷ and Brooks and Hansford.⁷²utton was inoculated with spores of *Mucor mucedo* and stored at -1°C. (30.2°F.) until growth had started, after which it was stored at -11°C. (12.2°F.) for four and one-half months. After this period, no evidences of black spot appeared, but merely usual growth of *Mucor mucedo*. Similar results were secured with *Penicillium glaucum*. Brooks also stated that the black mycelium of *Cladosporium herbarum* might be the cause of black spot and that in attempting to isolate this fungus special precautions should be used to secure the fungus since it grows deeper in the tissues than the other molds.

As stated above, growth of fungi on the surface of meat probably does not affect its use as food. Butjagin⁷³ studied the changes brought about in meat by *Penicillium glaucum* and *Aspergillus niger*. It was found that the growth of these molds caused a loss in dry matter and nitrogen and an increase in the amount of water-soluble nitrogenous bodies. The percentage amount of ether extract in the dry matter diminished, especially during the first month, and the amount of extractives was markedly increased, while the alkalinity of the meat increased slowly, being greater in the case of *Penicillium glaucum* than in the case of *Aspergillus niger*. By growth of these molds a gradually increasing amount of volatile acid was produced. The effect on the production of other bodies is also spoken of, the general conclusion being reached that the *Penicillium* studied destroys the constituents of meats more quickly than the *Aspergillus*.

Temperature and humidity are just as important in development of molds on meats as they are for bacteria. This was shown by Kaess.⁷⁴ Indif-

ferent control of temperature may enable common molds to develop on meat, according to Wright.⁷⁰ When the temperature is lowered, black spots appear where the molds have grown. He stated that meat stored below -9°C . could be kept for years with no black spots. The whole question of molds in meat and its products was studied by Lewis and Yesair⁷⁵ (quoted from Moulton, 1929). They isolated a rather long list of molds from several meat products. Pure cultures were subjected to the action of several disinfectants, among which sodium hypochlorite seemed to be most suitable under plant conditions. It was stated, however, that use of this compound should not supplant ordinary cleaning procedures. It was advised after cleaning as a supplementary procedure.

According to Haines,⁷⁶ who followed the development of bacteria on chilled and frozen meat, *Sporotrichum carnis* is able to develop at -5°C . (23°F .) and -7°C . (19.4°F .) on supercooled agar. In no case did the organism grow on frozen agar. Growth of molds on frozen meat in cold-storage lockers was observed by Semenwick and Ball.⁷⁷ The species identified were those mentioned throughout the discussion above.

FROZEN MEAT

Much meat is now frozen solid to preserve it. Meat which was frozen by the older slow methods usually yielded much "drip" after it was thawed. The newer methods of quick-freezing have largely corrected this. Microbial development is markedly retarded but not entirely eliminated by freezing. Haines⁷⁶ stated that a temperature of -5°C . (23°F .) was not sufficiently low to inhibit growth on frozen meats; -10°C . (14°F .) was satisfactory. Haines'⁷⁶ experience with a carcass of frozen mutton held at -5°C . (23°F .) showed a steady drop in numbers of organisms growing best at 37°C . (98.6°F .). On the lean portions of the carcass, after the initial drop, there was marked rise in bacterial numbers of organisms growing on gelatin at 20°C . (68°F .); no such rise was observed on the connective tissue of the carcass. These colonies were largely yeasts and molds. Occasionally a few rods of the fluorescent type were found. In no case was visible growth observed on carcasses stored at -10°C . (14°F .) and below. These organisms, according to Young⁷⁸ are contaminating forms which come from soil and which will grow at -1°C . (30.2°F .). He found that 10 to 20 per cent of carbon dioxide in the atmosphere would restrict their growth and not affect the meat.

Pictet and Young⁷⁹ exposed a number of common bacteria to a temperature of -70°C . for 108 hours and -130°C . for 20 hours. In general, they were not destroyed, although the virulence of some bacteria was decreased. Koch⁸⁰ showed that *Vibrio comma* could resist -10°C . (14°F .) for 10 hours. Macfadyen⁸¹ and Paul and Prall⁸² found living cells after exposure to liquid air temperatures (-190°C .), the latter after 100 days. Those which were maintained at room temperature died out rather rapidly.

Similar conclusions were reached by Sedgwick, Hamilton, and Funk.⁸³ Ruata⁸⁴ found that long exposure to temperatures below freezing was detrimental to bacteria, a conclusion which holds probably only for the organisms and conditions with which he worked. Angkiehong⁸⁵ observed marked variations in resistance to freezing among strains of *Shigella dysenteriae*.

The effect of freezing on microorganisms is probably largely determined by some of the conditions which exist. Broadhurst and Gilpin⁸⁶ reported that hydrogen-ion concentration was an important factor. While their observations were made on ice cream, it is not unlikely that their conclusions could be extended to other foods. Moran and Smith⁴⁷ could not observe a change in the bacterial content of meat stored at 5°C. (41°F.) for 17 days.

Bacteriologists have, in general, stated that bacteria are not destroyed by freezing. This attitude has gradually grown up by faulty reasoning. Suspensions of bacteria have been subjected to low temperatures and, because living cells have been found by subculture, it was believed that freezing did not affect bacteria. Quantitative data indicate, on the other hand, that an appreciably high rate of death occurs. The fact that a small proportion of the cells in a suspension survive does not indicate that freezing has no effect on bacteria. Haines⁷⁶ also observed the same results.

The theoretical factors involved in freezing meat have received considerable attention since quick- or sharp-freezing was introduced. One objection to frozen meat is the separation of water as ice on the outside of the muscle fibers. When the meat thaws, this drains away, giving rise to what is called "drip" or "bleeding." The Annual Reports of the Food Investigation Board of Great Britain contain published observations on this phenomenon. Quick-freezing, as stated by Birdseye⁸⁷ and the Australian National Research Council, almost completely eliminates "drip." Slow-freezing was said to allow the formation of larger ice crystals which ruptured the meat aggregate more than the small crystals formed in quick-freezing.

Cold-storage meats are frequently covered with molds. They are not destroyed by low temperatures any more than are the bacteria. Consequently, if spores are present on the surface of the meat when it goes into the cooler, they may germinate. Chodat⁶³ found that spores of *Mucor mucedo* were resistant to cold. Spores of several species of molds were kept frozen in Chodat's laboratory for over three years, at the end of which time viable cells were still present. Some meat which had been in cold storage developed a "musty" odor. This was attributed by Haines³⁴ to *Actinomyces* which was found in straw and on other debris taken into the coolers on the feet of employees. Haines reported that the species studied would not grow much below 0°C. (32°F.) and if at all, very slowly. The optimum temperature for growth was 25 to 30°C. (77 to 86°F.). At 33°C. (91.4°F.) the cells of the organism began to be abnormal.

Effect of Freezing on *Trichinella spiralis* in Meat. Trichinosis is a health hazard in eating uncooked pork. It is due to infestation of fresh pork

with a worm, *Trichinella spiralis*, which lives endoparasitically in muscle tissue of swine. In view of the fact that it would be impossible to examine every hog carcass with the microscope, federal officials have enforced adequate refrigeration at below $-15^{\circ}\text{C}.$ ($5^{\circ}\text{F}.$) for at least 20 days. Ransom⁸⁸ had found that this would rid infested pork of the parasite. When meats were preserved by quick-freezing, experiments were carried out to determine how the parasite would be affected. Blair and Lang⁸⁹ found the larvae to be killed in a few minutes in ground meat at $-17.8^{\circ}\text{C}.$ ($0^{\circ}\text{F}.$). The parasite was active in all samples of pork which had been kept at $-17.8^{\circ}\text{C}.$ for 48 hours. Augustine⁹⁰ reported that quick-freezing at $-1.1^{\circ}\text{C}.$ ($30^{\circ}\text{F}.$) followed by one day's storage at zero would destroy the larvae.

Tenderization of Meat. Several different methods for tenderizing meat have been proposed. Tenderization by storage in coolers provided with ultraviolet light has been discussed in Chapter 1. It is based on storage of meat at 12.8 to $18.3^{\circ}\text{C}.$ (55 to $65^{\circ}\text{F}.$). At these temperatures, which are higher than the $2.2^{\circ}\text{C}.$ ($36^{\circ}\text{F}.$) ordinarily used in coolers, spoilage will take place. In order to inhibit it, irradiation of the meat with ultraviolet rays has been suggested. Loss of weight by dehydration is controlled by a relative humidity of between 85 to 90 per cent. Ultraviolet light is said to destroy bacteria on the surface of the meat and to maintain a practical degree of sterility on all sides of hanging beef without damage to the carcass or to workmen. The wave length is largely limited to 2537\AA . After the desired degree of tenderness has been attained, the meat is chilled to the usual temperature, from $.6$ to $3.3^{\circ}\text{C}.$ (33 to $38^{\circ}\text{F}.$). This process, then, is based on use of higher temperatures of storage to accelerate enzyme action in the tissues and use of ultraviolet rays to control development of microorganisms on the surface of the meat.

Another method for tenderizing meats involves use of papain prepared from juice of the papaya (*Carica papaya*), as described by Pulley and von Loesecke.⁹¹ Papain is dissolved in slightly acidified water to which other substances, such as alcohol and glycerin, may be added as preservatives. Various commercial tenderizers have been compounded in which this enzyme is the important constituent. Usefulness of these products as meat improvers depends upon their proteolytic activity. Balls and Hoover⁹² pointed out that pure papain has at least three kinds of activity: it digests protein, clots milk, and splits ammonium hippurylamid. The first activity is important when it functions as a meat tenderizer, while the second is generally used as a basis of a method for measuring the activity of papain preparations. It is prepared commercially in the tropics by scratching the unripe fruit and collecting the milky exudate in glass or china vessels. The milky liquid, which soon coagulates, must be rapidly dried at low temperatures to prevent spoilage. Balls mentioned the investigation of Hall who

found that commercial papain may have a high bacterial population, a fact not now generally considered by manufacturers of meat improvers. This fact may also be of great importance from the standpoint of public health if the bacteria added to the meat happen to be undesirable species. The preparation is painted on the meat with a brush and then allowed to stand for a short period. While experiments have been conducted to render hams tender by adding papain to the curing solution when such hams are vein-pumped, the Bureau of Animal Industry of the United States Department of Agriculture does not permit the practice in plants operating under federal inspection. This position seems to be based upon the fact that there would be an excellent opportunity for deception in the use of tenderizers by restaurants as well as the fact that the effect on health of long-continued consumption of meat tenderized with papain is not known. In some instances the use of meat tenderizers has been represented as shortening the time of cooking by a definite percentage, making it possible to cut every portion of the cooked meat with a fork, and finally as an aid to digestion. It has also been shown that papain preparations are not particularly stable but this phase of the problem is a little outside the present interest. Since tenderization of meat is hard to follow quantitatively, Gottschall and Kies⁹³ devised a simple method for this purpose. Ground meat was found to digest by papain much more rapidly than unground. The enzyme preparation did not penetrate pieces of meat very rapidly.

Another agent used for tenderizing meat is raw pineapple juice which contains the enzyme bromelin. This is an active proteolytic enzyme which will digest some 1,500 times its own weight of proteins. A small amount of the juice or ground fruit pulp may be spread over the meat to be tenderized. Some penetration of the meat may be secured by stabbing it with a fork. Ground meat is attacked much more rapidly.

Tenderized hams are discussed later in this chapter.

Ground Meat (Hamburg Steak). Comminuted meats have wide sale in the United States. They have received considerable bacteriological investigation. Since they may be made from meat scraps and handled carelessly, they are subject to marked bacterial development because grinding thoroughly distributes bacteria, releases juices, and provides a much larger surface for the bacteria. In order to restrict bacterial growth, some dealers have resorted to preservatives. A survey in California indicated the practice to be quite common. Baking soda and sulfur dioxide were used. Stiff fines were levied on those who were guilty.

Possibility of low-grade raw materials being used in the manufacture of Hamburg steak has caused food-control officials to search for methods of examination. Among those studied have been bacteriological procedures. Hoffstadt⁹⁴ studied the relation of the bacterial content of meat to the conditions under which it was prepared. Bacterial count of all samples showed great variation in relation to sanitary conditions and organoleptic tests. Hoffstadt believed that enumeration of anaerobic bacteria offered a

94. Hoffstadt. 1924. *Amer. J. Hyg.* 4, 33-42; 43-51.

means by which keeping qualities of ground meats might be measured. According to Weaver,⁹⁵ when meat putrefies, a change from coccus to rods occurs. Zeller and Beller⁹⁵ stated that until four hours had elapsed, there was little change in bacterial flora of ground meat. The size of pieces influenced the bacterial count. Scraps for preparation of ground meat should be clean and as fresh as possible. Dirt and age mean heavy bacterial contamination which, in turn, means prompt spoilage. Several investigators, including Brewer,⁹⁶ have examined such meat for *Escherichia coli*. Its colonies outnumbered those of other microorganisms. It is doubtful whether it could ever be used as an indicator of undesirable conditions. Putrefaction of ground meats seems to be caused by several common bacteria. According to Sirotinina⁹⁷ *Bacillus proteus* is quite active in this connection at temperatures above room temperature. *Escherichia coli* also produces decomposition at higher temperatures. Low-temperature storage was believed to inhibit action of these two bacteria.

Bacterial Standards for Control of Ground Meat. Just how valuable bacterial standards are for this purpose is a debated question. Mere plate-count standards of aerobic bacteria are probably of no more value than many such standards for other foods. The ground meat standards which have been suggested have been concerned with aerobic bacteria only. Marxer⁹⁸ suggested a bacteriological standard of not over 1,000,000 bacteria per gram for judging quality of ground meat. On the other hand, Zweifel⁹⁹ did not consider the bacterial count to have any value. He was unable to isolate objectionable organisms and could see little to be gained by merely estimating the number of bacteria present. Weinzirl and Newton¹⁰⁰ believed that Marxer's standard was too low, since practically all ground meats would be condemned. After consideration of various factors they believed that a standard of 10,000,000 per gram was more acceptable. Even with this standard they expected that 50 per cent of the samples might be condemned. They stated that if good sound meat was used, no difficulty would be experienced in keeping well within the 10 million bacteria per gram limit. Weinzirl and Newton later observed that after one year's storage at $-10^{\circ}\text{C}.$ ($14^{\circ}\text{F}.$) six of 10 samples fell within their proposed standard. LeFevre¹⁰¹ believed in a bacteriological standard but further believed that the Marxer standard was high enough. Anaerobic and liquefying bacteria were present in all samples. Weinzirl¹⁰² reported further work. The aerobic plate count had no significance so far as putrefaction was concerned. Strains of aerobic bacteria from the meat did not cause putrefaction when reinoculated into meat. On account of difficulties in taking legal action against unsatisfactory ground meat, Elford¹⁰³ at-

tempted to determine whether a bacterial standard could be used. He plated proper dilutions on plain nutrient agar and incubated the plates at 37°C.(98.6°F.) for 48 hours. Forty-one samples gave plate counts varying from 100,000 to 20 million colonies per gram. He finally adopted a limiting standard of 10 million. Portland, Oregon, adopted this standard making it an offense to sell any unseasoned ground meat the average bacterial count of which exceeded this standard. Average was defined to mean the "logarithmic average" of the plate counts of all samples taken during a period of not less than four days and including at least four samples taken on separate days. This standard has resulted in considerable improvement since it has been in effect.

Preservatives in Ground Meats. Use of chemical preservatives in ground meat products is as objectionable as it is unnecessary. The Bureau of Animal Industry in Order 211, Regulation 18, prohibited the use of sodium sulfite, a preservative which at one time was quite widely used. Boric acid was also used for this purpose, but is now prohibited in all food products. Stroscher¹⁰⁴ advised against the use of sodium sulfite in meats. Metzger and Fuchs¹⁰⁵ studied sodium benzoate as a meat preservative. After years of attempts to use chemical preservatives, the best practice now consists of the use of sound raw materials and adequate refrigeration. Sound raw materials mean a low bacterial load and a cleaner product. Until 1928, it was permissible to dust preserved meats prepared for export to England with boric acid. Boric acid has, however, been placed among the prohibited chemical preservatives by British medical officers of health.

Prevalence of use of preservatives in ground meat is probably not known. A survey of the practice carried out in California¹⁰⁶ revealed that 80 per cent of 50 establishments openly admitted the use of some type of preservative ranging from common baking soda to sulfur dioxide. Sodium sulfite was commonly used by some vendors.

Development of *Clostridium botulinum* in Meat Products. Spores of *Clostridium botulinum* are known to be widely distributed in soil. It is not improbable, therefore, that they are present at times on various meat products. Meat is an ideal medium for the development of *Clostridium botulinum*. Most of the media used in the laboratory consist of ground meat with added water. The several outbreaks of botulism traced to meat products constitute presumptive evidence that meats may carry the spores of *Clostridium botulinum*. Edmondson, Thom, and Giltner¹⁰⁷ inoculated meat balls with toxin-free spores and incubated them at 9°C.(48.2°F.), 20°C.(68°F.), and 30°C.(86°F.). Incubation at 30°C. caused the formation of enough toxin to kill a guinea pig in 18 hours. The sample was slimy and possessed a foul odor. At 9°C. no toxin was formed in three weeks. Thorough cooking would detoxify a product which had become toxic. Meat products have been conspicuously free from botulism when the large amounts which are preserved, are considered.

Microbiology of Sausage. Some parts of the carcass are made into sausage. For some types of sausage, the meat is ground and mixed with a binder, usually a starch product. The binder helps to make the sausage stand up. Binders are not now used as much in America as formerly. Spices are added to taste, and the meat is forced into a casing by a sausage stuffer. The casings are slipped over tubes connected with the stuffer. After the casing is filled or the sausage is stuffed, it is linked by giving the casing a twist at definite intervals. If the sausage is to be canned, it is not linked but is hung up to dry. This, in general, is the treatment for fresh sausage. Some sausage is smoked, but such a product is usually made from cured meats and is cooked in water for lengths of time which depend on the type of sausage. The dry sausages are, perhaps, set apart from those which have just been discussed. Their advent in the early days was probably due to lack of adequate refrigeration which drove the makers to drying sausage. Microorganisms may spoil sausage. This may occur during preparation or during storage and may assume different forms, according to Glasser.¹⁰⁸ The entire mass may be impregnated with bacteria which attack the protein and fat, often with gas formation. The sausage may spoil either at the core or at its outermost layers. Sausages which are held too long or at too high temperatures may become rancid if poor fat was used in their manufacture.

Microbiology of sausage is not unlike that of ground meat. The two products may differ, owing to the fact that sausages are often heavily seasoned; some spices have a germicidal effect on bacteria. While most of the work on sausage has been done with the idea of food poisoning in mind, a little has been carried out to determine the types and number of bacteria which are present in normal sausage. Slooten¹⁰⁹ found few bacteria in sausage; some were sterile. Drying, smoking, and plenty of spices tended to lower the microbial content. Sausages are usually stuffed into casings prepared from the gut of domestic animals. These casings are cleaned and pickled in salt. Savage¹¹⁰ found that salt solutions must be both concentrated and allowed to act for a long time to have much effect on bacteria. Komma¹¹¹ found it rather easy to isolate members of the *Salmonella* group (*Salmonella schottmülleri*) from sausage. Thirty samples contained this organism, while 35 contained *Escherichia coli*. Sacquepee and Loygue,¹¹² Rommeler,¹¹³ and Brekenfeld¹¹⁴ also found *Salmonella* organisms in sausage. Some samples had caused intestinal disturbances. From normal and abnormal sausages aerobic and anaerobic bacteria were isolated. He placed much importance on anaerobic, spore-forming bacteria as causative agents in food poisoning.

Cary¹¹⁵ made bacteriological examinations of sausages purchased on the market in Chicago. Each market from the which the sausage came

was scored for general sanitation, refrigeration, and other desirable features. *Escherichia coli* was isolated from 30, *Proteus vulgaris* from 11, *Staphylococcus* from two, etc. Cary's observations led him to conclude that the casings could not be considered to increase the bacterial count or danger from pathogens. Six samples of pork sausage were cooked in the laboratory in various ways, to determine the hygienic value of home cooking. Four samples cooked in a restaurant were also examined. Ordinary cooking destroyed most of the bacteria, while extra cooking destroyed them all. Guerin's¹¹⁶ results were similar. Kühl¹¹⁷ considered the microorganisms on slimy sausage to be of importance. Gauducheau¹¹⁸ isolated an organism from curing sausage to which he gave the name *Bacillus creatis*. The organism was neither pathogenic nor toxicogenic. It was believed to have some relation to curing and development of proper flavor.

Yeasts also seem to have a role in curing of sausage and formation of slime on the surface. Cesari¹¹⁹ and Cesari and Guilliermond¹²⁰ believed that certain yeasts contributed to the good quality and flavor of these products. Three closely related species were isolated which grew best in media poor in carbohydrates and in the presence of 10 to 15 per cent of salt. An agreeable aroma was formed in protein media. Cesari said that inoculation of the meat during sausage manufacture improved the flavor and prevented putrefaction. All of the species isolated by Cesari and Guilliermond¹²⁰ belonged to the genus *Debaromyces*, with exception of a few species in which spore formation could not be established. Mrak and Bonar¹²¹ found the species from fresh sausage to be *Debaromyces*. They believed the species to be *Debaromyces Guilliermondii* var. *nova zeelandicus*, Lodder, 1932. Mrak and Bonar did not discuss the significance of these species in sausage. Bacteria as well as yeasts, according to Moser,¹²² are related to flavor of sausage.

Some sausages are heavily spiced. While most spices would be too weak to cause inhibition, a few are known to possess germicidal properties. Danielson¹²³ stated that the amounts of garlic and onions usually used in sausage had no effect on growth of putrefactive or pathogenic bacteria.

Slimy Sausage. This is due to the growth of bacteria on the surface of the sausage. It has been stated now and then that yeasts are the cause of this spoilage. This is probably due to the appearance of the sausage and not to data which have been collected in bacteriological examinations. Sausages are probably inoculated by coming into contact with contaminated objects. Cooking of sausage has been found to reduce, if not completely prevent growth of the offending bacteria. Care must be used after cooking to prevent reinfection. This problem was studied by Roderick and Norton.¹²⁴ They stated that a temperature of 73.9°C.(165°F.) maintained for

124. Roderick and Norton. 1926. Quoted from Moulton's Meat Under the Microscope.

15 or 20 minutes should provide an ample margin of safety above the thermal death point of the cocci. Schroder¹²⁵ described ropiness in sausage which he found was due to cocci; they grew best on blood and serum agar and were nonpathogenic for men and white mice. The only change observed in the sausage was ropiness.

Botulism From Sausage. Sausage has caused a few outbreaks of botulism in America and Germany. It has never been an important food in this respect, and the epidemiological evidence of some of the outbreaks leave much to be desired. According to Bitter,¹²⁶ cooking applied to sausage may be a procedure of some hygienic value. The toxin does not resist high temperatures and would probably be destroyed by cooking in the home. Bitter showed, however, that heat penetration into sausage is not rapid. Large sausages may require cooking for perhaps 30 minutes to detoxify the interior portions.

The spores of *Clostridium botulinum* are in another category. They are so resistant to heat that many types of sausage could not endure a botulinus cook. The danger of insufficient cooking of sausages is illustrated by an outbreak of poisoning among German troops on the Verdun front reported by Baerthlein.¹²⁷ In order not to remove the fat, sausages were cooked for but 30 minutes, while it had been shown that 45 minutes were required for satisfactory results. Reports of several outbreaks of botulism attributed to sausage are available in the literature. So-called summer sausages are in a different category, according to Hall,¹²⁸ who reported that *Clostridium botulinum* failed to grow and produce toxin in them even when large numbers of viable spores were inoculated in several places and the sausages incubated at 37°C. (98.6°F.) for as long as eight weeks. They spoiled, however, in a few hours when placed in water at 37°C., and strong toxin developed in a few days if they had been inoculated with *Clostridium botulinum*.

Green Rings in Sausage. Green rings occur in sausage about one-eighth of an inch from the casing. According to Lewis and Jensen,¹²⁹ the cause is bacterial. They demonstrated that improvements in methods of manufacture which tended to decrease the total number of bacteria in the product at all stages, tended to prevent the development of green rings. The green substance was believed to be methemoglobin. The appearance of the green ring does not indicate that the sausage is unwholesome. Jensen and Urbain¹³⁰ have stated that "undercuring" is the explanation given by many practical men in the industry. While some discolorations in meats may be due to undercuring, others are due to chemical changes in which bacterial activity is concerned. Jensen and Urbain found that the microorganisms responsible for formation of green pigments in meats and blood agar are those which oxidize hemoglobin, nitrosohemoglobin, nitrosohemo-

chromogen, and hematin. In addition hydrogen sulfide-forming bacteria cause green discolorations in meat and blood agar. The species of bacteria involved were members of common genera which were found in meat products.

Attempts have been made to use preparations for preserving sausages. Pieltre¹³¹ coated them with gelatin, a practice condemned by Bardas.¹³²

Brekenfeld¹³³ introduced a "bacterioscopic" method of sausage examination which revealed presence of both dead and anaerobic bacteria which would not appear in cultures. The results of this procedure applied to meat trimmings from 48 slaughterhouses agreed well with the sanitary conditions which obtained in the houses. The method involves examination with the microscope of stained sections made from various parts of the sausage. The bacteria are revealed in this manner. Moser¹³⁴ used the method but did not find it so satisfactory that it could replace older tried methods. Some satisfactory sausages were said to contain bacteria distributed as they are in putrid samples. Furthermore the method could not be used in control work. A histological method of sausage examination was proposed by Thorp and Coburn.¹³⁵ Many foreign materials could be detected. The most important pathological condition is the presence of trichinella cysts.

Sour Beef. This is a trade description of spoilage¹³⁶ occurring in freshly slaughtered beef which has not been properly cooled. Bunyea¹³⁷ studied the question and quoted the following from Ostertag: "Stinking acid fermentation occurs in slaughtered domestic animals when the meat, while still warm, is stored in large pieces and in closed receptacles, or in general, when it is subjected to conditions under which it can not cool. This alteration is characterized by the term 'suffocated'." Bunyea was unable to state whether the spoilage studied by Ostertag was identical with the sour beef which he studied. Bunyea isolated an organism which was thought to be the causal organism. He published a complete description of it.

The organism was said to be an aerobic saprophyte with a wide range of temperature for growth, but with an optimum around 37°C.(98.6°F.). Serological studies identified the organism with *Bacillus megatherium*. Bunyea reported that souring of beef was due to formation of propionic acid. The organism which was isolated was found to be nonpathogenic for guinea pigs, and not to produce toxin in broth or raw beef. Another experiment was also instituted to compare the odor produced by the organism *Bacillus megatherium* and a number of pure cultures of common organisms. None of them were able to reproduce the odor of sour beef. Packers have learned that this type of spoilage can be markedly reduced by rapid chilling of meat. In fact, many defects of meat have been reduced, if not

136. The term "sour" in this spoilage does not mean acid, but rather putrid. Sour beef has all the evidences of putrefaction.

137. Bunyea. 1921. J. Agr. Res. 21, 689-698.

completely eliminated, by prompt and adequate chilling. Haines²⁹ connected another organism to "sour" beef. The beef upon which he worked became sour a few days after slaughter. An organism which belonged to the fluorescent group was isolated as the cause.

Bone-Taint of Beef. Moran and Smith⁴⁷ applied this term to certain putrefactive changes which occur in the neighborhood of the hip joints of otherwise prime carcasses. These changes are accompanied by a bad odor. While the evidence suggests that it is of bacterial origin, some confusion exists in explaining just how infection occurs.¹³⁸ One theory, according to Moran and Smith, is that infection proceeds along the iliac arteries into which bacteria gain access during dressing. Other evidence connects its appearance with fatigue of the animal before slaughter. Meat packers have learned the value of handling animals carefully and giving them plenty of water. Rapid cooling of the carcass is now known to be important in preventing this defect, just as it is in other undesirable spoilage. An aerobic, sporeforming rod was isolated from synovial fluid and tissues in and about the hip joint of a beef carcass with "bone-taint" by Haines and Scott.¹³⁹ It resembled *Clostridium oedematiens* very closely. Examination of 40 hip joints from normal carcasses indicated that 38 were sterile, one heavily infected with a *Streptococcus*, possibly of the *fecalis* type, and with a rod, probably a member of the *Proteus* group.

SMOKING OF MEATS

This is in reality a chemical method of preservation for products of incomplete combustion of wood, corncobs, or other materials are left on the meat. While some of them are permitted in and on meat when they originate in smoke, they are prohibited when added as the pure substance. The Food, Drug, and Cosmetic Act of 1938, interprets that any substance added to food by the process of curing known as smoking, shall not be considered a preservative.

While "liquid smoke" preparations are used by home curers of meat, these preparations are not used by the large packers for two reasons, mainly: they do not give as good results, flavor, and preservative value as does smoke from hardwoods and they are prohibited by the Bureau of Animal Industry for products prepared under federal inspection and intended for interstate shipment.

Various materials may be used as sources of smoke. Corncobs have been used for some time for smoking meats under domestic conditions. Hickory wood has been much used under commercial conditions. One writer stated that in Germany juniper berries are used for smoking Westphalian hams. When hickory is used, the logs are burned under the hams. Toward the end of the period, hickory sawdust is thrown on to give the hams a brown color. Meats which are smoked have usually been pickled. Smoke is used to improve flavor and to act as a preservative. The length of time required for smoking depends on the size of the piece of meat and results desired.

139. Haines and Scott. 1940. J. Hyg. 40, 154-161.

Smoked meats are subject to attack by molds which grow in moisture on the surface. Consequently, care is used in packing houses in storage of smoked meats. They are smoked and shipped as soon as possible thereafter.

The chemical compounds imparted to meat by smoke have not been extensively studied. Callow¹⁴⁰ found that smoked bacon and ham gave a strong reaction for formaldehyde. Estimates of the amount of formaldehyde content of commercial smoked herring, bloater, kipper, ham, and bacon gave amounts ranging from .5 to 1,000 parts per million. Hess¹⁴¹ stated that formaldehyde in smoke gives it its bactericidal properties. Vapors, containing three or more grains of formaldehyde per 1,000 cubic feet, approximately the same concentration that is found in smoke, had a definite bactericidal action. While it is quite definitely known that formaldehyde in smoke is germicidal, it is also possible that other constituents may also be germicidal.

Formaldehyde is a prohibited preservative when added to food as such. However, food laws make exception to that which is in smoke. Buchanan and Schryver¹⁴² reported results of actual experiments with dilute solutions of formaldehyde in meat preservation. At that time, much of the meat shipped from South America to England was fumigated on ship-board. Claim was made that the formaldehyde was not absorbed by meat. Buchanan and Schryver's experiment's however, showed that it was present, not only on the surface, but underneath, especially where muscular tissue had not been covered with fat. Meat products with large surface per unit weight must, therefore, absorb considerable amounts.

It is known that smoked meats may contain substances from smoke which cannot be added as such. When wood is distilled in absence of air, methyl alcohol is formed which may be oxidized to formaldehyde. Other substances found to be present are higher aldehydes, ketones, formic, acetic, and higher acids, water, and alcohols.¹⁴³ Good smoking practice, according to Jensen,¹⁴⁴ teaches that most cured meats should not be held in the temperature zone of 18.3 to 40.5°C. (65 to 105°F.) for longer than eight hours. He revealed that some bacteria are resistant to smoke while others are killed. Wieser¹⁴⁵ smoked a piece of infected ham until it was completely cured but observed that bacteria were not killed at one centimeter or more beneath the surface.

SALTING OF MEATS

Pettersson¹⁴⁶ showed that the preserving effect of salt in fish and meat was gradual and not sharply defined. Salt was found not to act uniformly on all bacteria but to possess a selective action. Obligate anaerobes were

found to be inhibited by five per cent concentration; above five per cent, facultative anaerobic and aerobic species developed. Of the cocci and rods which brought about intensive decomposition, the rods were more easily harmed by salt. Most of them were repressed by 10 per cent concentration, although a few developed up to 15 per cent. Most cocci seemed to be able to tolerate 15 per cent. Yeasts appeared in media with greater amounts of salt. DeFreytag¹⁴⁷ studied the question with pathogenic bacteria. Spores of *Bacillus anthracis* were still alive after six months' sojourn in saturated salt solution. The vegetative cells were destroyed in a few hours. The limits for germination of spores in bouillon at 37°C. were between seven and 10 per cent. *Eberthella typhosa* was viable after six months in concentrated salt solution. The organism of hog erysipelas was viable after two months. *Mycobacterium tuberculosis* was not destroyed in three months. Stadler¹⁴⁸ was interested in determining whether meats could be freed from pathogenic bacteria by curing in salt solutions. *Escherichia coli communis* survived seven to eight per cent of salt in solution for six weeks. *Bacillus moribificans bovis* died in a solution of seven to eight per cent of salt in three weeks. *Salmonella enteritidis* in a solution of seven to eight per cent of salt died in four and one-half weeks. *Bacillus proteus vulgaris* did not die in this concentration in three weeks. The limit of salt concentration which inhibited growth of bacteria was 10 per cent. Forster¹⁴⁹ also believed that curing would not necessarily kill pathogenic bacteria in meat. Weichel¹⁵⁰ reported that such bacteria as *Salmonella enteritidis* and *Salmonella schottmülleri* could live for 33 to 95 days, depending on the salt concentration and the temperature. At refrigerator temperatures, there was good development in all concentrations after 71 days. It was also indicated that the number of cells inoculated into the cultures influenced the results. Bacteria inoculated into meat before pickling died so slowly even in strong (19%) brine that pickling could not be said to make infected meat safe. Inoculated meat kept in 12 to 19 per cent of salt showed complete bacterial destruction only after 75 days. In 10 to 13 per cent salt solutions, many living bacteria were present in the interior of the pieces after 80 days. Quite similar conclusions were reached by Karaffa-Korbitt¹⁵¹ and Serkowski and Tomeczak.¹⁵² This review of literature indicates quite clearly that salt in concentrations that could be used in food preservation is not a bactericide but perhaps a preservative for a few species of bacteria.

As an example of an organism which thrives in concentrated brine may be mentioned *Bacteroides halosmophilus*, Baumgartner.¹⁵³ Maximum growth occurred at salt concentration between 12½ and 15 per cent of salt. The organism is a strict anaerobe, the heat resistance of which is influenced by the salt concentration.

Some work has been done to show that salt itself may carry undesirable bacteria. Rappin¹⁵⁴ isolated bacteria from crude and refined salt which caused defects in butter and cheese. Weigmann¹⁵⁵ and Wolff¹⁵⁶ confirmed this work and showed that salt for food preservation should be carefully handled and protected from undue contamination. Yesair¹⁵⁷ found a variable bacterial content in salt. The total counts ranged from 0 to 1,470 per gram in a series of 125 samples. He stated that in the process of refining salt practically all of the bacteria are destroyed. Putrefactive anaerobes, however, were found in mined salt. On account of this Yesair advised against the use of such salt in the meat-preservation industry.

Tanner and Evans¹⁵⁸ observed that strains of microorganisms differ in their resistance to salt. The substrate to which the salt is added has much influence. The amounts of salt which inhibited *Clostridium botulinum* were around 10 per cent. Further data on this question have been reported by Callow.¹⁵⁹ Portions of minced pork were placed in stoppered bottles and various weights of salt added. The bottles were stored at 0°C.(32°F.). After two months the pork with no added salt had putrefied. That with even two per cent of salt had not. Its surface was covered with mold and yeast colonies but no bacterial colonies were visible. Between two and seven per cent, colonies of these organisms became fewer. Above nine per cent, no colonies of any kind could be observed with the naked eye. With the microscope, however, yeast cells and mold spores could be detected in samples containing up to 16 per cent of salt. Then all samples with more than seven per cent of salt were placed at room temperature. In a few days mold growth appeared on the meat containing 11 per cent of added salt but not on meat with 12 per cent or more. Callow confirmed the observation that salt exerts not only a repressive action but a selective action as well. The latter is more pronounced at 0°C. than at room temperature.

DRYING OF MEATS

Exigencies of the world war prompted inquiries into the possibility of drying meats which were to be shipped abroad. Kraybill^{159a} mentioned three advantages, conservation of shipping space, conservation of metal containers and to furnish a product which would keep well without refrigeration. He stated that results of experimental work indicated a safe product was secured when prepared according to federal specifications which were quoted for beef. The meat has to be dried so that it contains not more than ten per cent of moisture in any particle when placed in the container.

Another type of product similar to dry or summer sausage, studied by Ritchell, Piret, and Halvarson,^{159b} underwent a rapid decrease in viable

bacteria during storage in vacuum cans. In forty-nine weeks counts of 21,800,000 in samples containing 28 per cent of water had dropped to 180 bacteria per gram; samples with 25 per cent of water decreased in this time from 24,300,000 to 110 bacteria per gram.

CURING OF MEAT PRODUCTS

Carcasses of hogs are chilled as soon as possible after slaughter and dressing. They are placed in coolers until chilled throughout. When the time comes to cut the carcass, it is brought from the cooler to the cutting floor. Cutting is one of the most important steps in its preparation. The carcass must be cut in such a manner that the packer will receive the greatest return. Certain cuts, which will yield the greatest return, should not be trimmed more than necessary.

Chief among the cuts to which the packers give special attention are the hams. Cutting of hams is the first operation on the cutting floor and one which requires considerable care and skill. Carcasses which are cut at one time have usually been graded for size and weight; consequently, cutters will work for a time on one lot. Cuts are thus kept uniform in weight. Hams are cut from the carcass by sawing at proper angles in order to secure as much of the desirable tissue as possible, as well as to leave as much as possible on certain other cuts. Considerable attention is also given to the shape of the hams. Shoulders are chopped and cut from the carcass and are usually not trimmed to the same extent as are hams.

After the hams have been cut and trimmed, they are ready for the curing cellar. Attention is given to the temperature of the hams when they are ready for the curing pickle. Packers have learned that the temperature should not be above about 2°C. (35.6°F.). This temperature is given as 38°F., by some packers. This matter is carefully watched and if the temperature is too high, the hams are placed again in the cooler in such a manner that the temperature may be lowered to the desired point.

One of the first steps in curing hams is "pumping" or forcing a certain amount of curing pickle into the ham. The solution is placed in a barrel provided with a force pump, each stroke of which delivers a known amount of the curing pickle. The pickle is conducted into the ham by means of a hollow needle or tube fastened to the pump by means of rubber tubing. Pumping the ham in this manner insures entrance of the curing pickle into the ham far more quickly, of course, than it could penetrate from the exterior. It is also necessary to have the cure start throughout the ham as soon as possible. Especially important in this respect is the area in the ham about the bone where undesirable changes may start in a short time. Not all hams are pumped, but this treatment is given hams which go through the usual routine of the meat plant. The curing or pickling solutions are made from salt, sugar, sodium nitrate or sodium nitrite, or both, and water. Another method of pumping is known today as vein-pumping in which the curing solution is forced through the veins for better distribution.

When hams are to be subjected to the effect of the pickling solutions, they are packed tightly into various containers. Tierces, or large casks, may be used. Vats or tanks made of concrete may also be used. Hams must be packed carefully into these containers in order that there shall be a good circulation of the pickle and as even penetration into the meat as possible. The shape of the hams must also be considered. The length of cure is determined to a great extent by the weight of the ham, the concentration of the curing pickle, temperature, etc.

During curing a temperature of $3.3^{\circ}\text{C}.$ ($38^{\circ}\text{F}.$) is maintained because if a lower temperature is used, the cure is retarded and a high temperature may cause defects in the curing solution although curing may be accelerated. Some of the results of using various temperatures on behavior of spoilage organisms have been published by Tucker.¹⁶⁰ In general it was found that a temperature of $3.3^{\circ}\text{C}.$ ($38^{\circ}\text{F}.$) would suppress spoilage. Tucker also studied the effect of temperatures $1.1^{\circ}\text{C}.$ ($34^{\circ}\text{F}.$) and $5.5^{\circ}\text{C}.$ ($42^{\circ}\text{F}.$). One organism which he used in his experiments, *Clostridium putrefaciens*, was not hindered much at these temperatures while the other three were. Consequently, possibility of spoilage must be considered even at quite low temperatures. The physical changes which are involved in ham curing are diffusion of salt, nitrate, nitrite, and sugar into the meat and passage of soluble substances from the meat (Greenwood *et al.* ¹⁶¹).

During the past few years the old methods of curing which required about 90 days' sojourn in curing solutions, have been replaced by some packers with a "quick-cure" requiring only a few days. Hurd¹⁶² stated that this method of curing was here to stay. The use of a stronger curing solution over a shorter time was believed to give a superior product.

Effect of Sodium Nitrate (Saltpeter) on Bacteria. Sodium nitrate has been used so long in meat-curing solutions that its origin is probably unknown. Sausage has been cured with this salt for much over 100 years, and other meat products have probably been cured with it for much longer. When this salt is not used, the meat has a dull, uneven color instead of the bright, red color commonly connected with cured meats. Early students of meat curing generally attributed the value of nitrate to its color effects, but more recent work seems to indicate that it may possess some value as a preservative when used in combination with salt and sugar. When used alone, it may show feeble bactericidal action, as indicated by MacNeal and Kerr.¹⁶³

It is difficult to find results of experiments on the effect of sodium nitrate on bacteria, and many of those which are available are not directly applicable to problems related to meat curing. Statements appear in books to the effect that the nitrate is reduced to nitrite, the latter compound exerting a detrimental effect on bacteria. Crespolani¹⁶⁴ mixed one gram of potassium nitrate with 300 grams of horse flesh and reported that putre-

164. Crespolani. 1905. Boll. Farm. 44, 697-700.

fraction resulted with complete reduction of the nitrate. According to Serafini¹⁶⁵ a five-per cent solution of nitrate exhibited very little antiseptic action. Pettersson¹⁴⁶ reported that meat and fish with from five to 15 per cent of saltpeter putrefied when kept at 25°C. (77°F.). However, it was shown that mixtures of small amounts of saltpeter and salt were active antiseptics. MacNeal and Kerr,¹⁶³ as a part of an extensive investigation on the influence of saltpeter on the nutrition and health of man with reference to its occurrence in cured meat, studied the effect of sodium nitrate on bacteria. It is unfortunate that they did not use strains of bacteria which were of greater significance in the meat-preservation industry. They used *Escherichia coli*, *Clostridium welchii*, and an unidentified *Bacillus* "Type VIII." They found that potassium nitrate in neutral or alkaline solutions exerted no special restrictive effect on bacterial activity. Under these conditions it was used as food. In acid solutions, however, the results were quite different. A marked bacterial inhibition was noticed. They said that this effect was incomparably greater than that of the corresponding chloride and was best ascribed to the production of small amounts of nitric acid, and of nitrous acid also, in mixtures containing reducing substances. Potassium nitrate was therefore considered to be particularly effective in restricting acid fermentation of organic substances already slightly acid. They further believed that the claim of meat packers, that small amounts of nitrate in meat pickle produced better preservation of the meat, was borne out by their results. It seemed that nitrate was especially valuable in preventing high degrees of acidity or souring of meat. MacNeal and Kerr stated that the effect of saltpeter was probably due to the oxidizing action of the nitrate ion in the presence of hydrogen ion. Stadler¹⁴⁸ gave a formula for a curing mixture which consisted of 250 grams of salt, 10 grams of saltpeter, 30 grams of sugar, and one-half of a glass of red wine. He believed that the sugar and saltpeter functioned only as a color fixative.

In relatively high concentrations, sodium nitrate may have a deleterious effect on bacteria, according to Lewis and Moran¹⁶⁶ who found that 4.4 per cent of this salt was completely effective in checking the proteolytic activity of *Clostridium putrefaciens* in pork-infusion medium. This organism did not reduce nitrate to nitrite so there was no germicidal effect of the latter. A specific effect was exerted on the proteolytic activity of *Clostridium sporogenes* between the concentrations of .5 and 1.0 per cent of sodium nitrate. When salt was present, a combination of five per cent sodium chloride and one per cent of sodium nitrate inhibited proteolysis by this organism. This large amount of nitrate required to inhibit bacterial action would indicate that saltpeter alone could have little significance in meat curing and preservation.

Lehmann¹⁶⁷ and Hoagland¹⁶⁸ found that the nitrate, as such, did not influence the color, but that it had to be reduced to nitric oxide in the

meat. The red color was said to be due to nitric oxide hemoglobin which is formed by the action of nitric oxide on hemoglobin. In a later publication, Hoagland¹⁶⁹ reported confirmation of his earlier work. A much later contribution was made by Bernheim and Dixon,¹⁷⁰ who, in attempting to determine the nature of the oxidation-reduction systems in tissues, found that muscular tissue of oxen, sheep, pigs, rabbits, dogs, and chickens would not reduce nitrate to nitrite. The same kind of tissue obtained from rats and guinea pigs possessed this power. Liver tissue was found to be capable of this reduction regardless of the species from which it was taken. This would seem to indicate that some factor other than the meat itself was responsible for the reduction of nitrate to nitrite in cured beef and pork.

Nitrate may apparently be changed into other compounds than nitrite by anaerobic bacteria. Prevot¹⁷¹ listed many common anaerobes which do not reduce nitrates but cause it to disappear. The only strict anaerobe known to reduce nitrate is a new species, *Eubacterium nitritogenes*, isolated by Prevot. The results of investigations by Riess, Meyer, and Müller¹⁷² on use of sodium nitrate and sodium nitrite in meat preservation in Germany are pertinent. Since 1916, addition of nitrites to meat products has been against the law, but attempts have been made to have the prohibition of its use nullified. It was appreciated that nitrate which is permitted is reduced to nitrite and that, could nitrite as such be added, great saving of time could be accomplished (about one-third). The experiments carried out by Riess, Meyer, and Müller were instituted to answer several questions: (1) Does the addition of sodium nitrite to meat-curing solutions injure the health? (2) Is the saving of time of such significance that nitrites should be used, even though they may be somewhat poisonous? (3) Does the meat pickled with nitrite have the same characteristics as meat pickled with nitrate? They found that the use of nitrite instead of nitrate permitted a much more rapid cure. They also stated that the use of nitrite caused more rapid infiltration of salt. They were unable to detect any appreciable difference in the appearance or keeping qualities. Nitrite content of cured meat was said to be smaller when a nitrite cure was used than when a nitrate cure was used. From 10 to 20 milligrams of nitrite per 100 grams of meat were found in the outer layers, while one-tenth as much was found in the inner layers.

The experiments referred to above, by Riess, Meyer, and Müller, also included study of the bacteria involved. They stated that a review of the literature indicated a confused state of knowledge with regard to the part which bacteria might play in reduction of nitrate. Polenske¹⁷³ believed that bacteria were involved in reduction of nitrate in curing solutions. Nothwang¹⁷⁴ took the opposite view. Maassen's¹⁷⁰ experiments indicated a marked action of bacteria on nitrates. Of 109 bacteria, 85 were able to

reduce nitrates. Riess, Meyer, and Müller conducted experiments to secure information on this question, using, as far as possible, conditions which would obtain in practice. It was noticed by these investigators that better results were secured in wooden barrels than in jars. This situation could not be explained by bacterial contents. Six pure cultures were isolated which were, in turn, used in pure-culture inoculations. Without giving all of the experimental details, it may be stated that large amounts of nitrite were formed only in those flasks which contained meat, showing that some food substances must be present for formation of nitrites. Some bacteria could not form nitrite in the absence of meat, and only a small amount in the presence of it. Temperature was said to have little effect, since the amounts of nitrite formed at both low and high temperatures did not differ materially. Attempts were made by Riess, Meyer, and Müller to follow formation of nitrites from nitrate without presence of bacteria. It was found, however, that bacteria had gotten into these flasks. No conclusions could be reached.

Considerable work has been carried on on the effect of sodium nitrite and nitrate on spoilage bacteria in the meat, as well as on *Clostridium botulinum*. Results of these investigations will be reviewed at greater length.

The Institute of American Meat Packers sponsored an investigation, results of which were reported by Moulton.¹⁷⁶ This work was done with several organisms isolated from spoiled hams: *Clostridium sporogenes*, *Clostridium putrificum*, and *Clostridium putrefaciens*. They were inoculated into media prepared from pork and their action followed by determining the amount of protein cleavage products which were formed. At 37.5°C. (98°F.) five per cent of salt or one per cent of nitrate retarded the action of *Clostridium sporogenes*. Five per cent of salt and one-half to one per cent of nitrate showed still greater inhibition. When two per cent of nitrate was added to five per cent of salt, spoilage was prevented. It was shown that bacteria were not killed; they were merely inhibited and were unable to attack the meat. When sodium nitrite was substituted for the nitrate in a medium containing no salt, .05 per cent prevented spoilage. Nitrite was thus found to be more active in preventing spoilage than nitrate. Experiments were then undertaken to determine the results that would follow the use of less salt. Three to four per cent solution or .9 per cent of nitrate alone showed some inhibition. When nitrite was used in place of nitrate, it was found that one per cent of salt and .15 per cent of nitrite prevented all action.

Similar experiments were also made, using curing cellar temperature, 4.4°C. (40°F.). Pieces of beef were placed in the different curing solutions and allowed to cure for 21 days. At the end of this time, all of the curing solutions, even those with 15 per cent of salt, showed visible growth, while a .25-per cent nitrite curing solution showed no growth. Further experiments all indicated some activity of sodium nitrite in inhibiting bacterial growth.

175. Maassen. 1902. Arb. aus dem K. Gsndhtsam. 18, 21-77.

176. Moulton. 1929. The Canner, 1930. Conv. Number.

While meat packers once desired a nitrite cure, results of extensive investigations have indicated, at times, that a mixed cure (containing both sodium nitrate and sodium nitrite) is desirable from the standpoint of both spoilage and development of toxin by *Clostridium botulinum*. The preserving effects of such curing solutions have been generally attributed to the nitrites, either those added as such or those secured by reduction of the nitrate; however, some evidence was believed to indicate that nitrate itself may have some value as a preservative. This is a controversial subject.

Much study has been given to the chemical mechanisms by which sodium nitrite imparts the desirable red color to meat. Probably the actual facts are still unknown. Among those who have contributed to the subject are Polenske,¹⁷³ Nothwang,¹⁷⁴ Kisskalt,¹⁷⁷ Pettersson,¹⁷⁸ Haldane,¹⁷⁹ Hoagland,¹⁸⁰ and McBryde.¹⁸¹ The subject is mainly a chemical problem. Haldane stated that red color of cooked meat, preserved with curing solutions containing sodium nitrite, was due to NO-hemochromogen. This compound was said to be produced by the decomposition of NO-hemoglobin by the meat, which caused the red color. NO-hemoglobin was said to be formed in the absence of oxygen and in the presence of reducing agents.

Hoagland¹⁸² believed the action of saltpeter in influencing the color of meat to be due to the formation of oxyhemoglobin. Saltpeter was reduced within the meat to nitrites which, in turn, were changed to nitric oxide. This united with the hemoglobin to give the characteristic red color. Saltpeter, which is used in many pickling solutions, probably exerts little effect on bacteria.

Food-control officials have justly shown concern over the addition of sodium nitrite to meats. As stated above, the Bureau of Animal Industry placed a limit of 200 p.p.m. in the cured product. Much depends on how the determinations are made. If determinations are made on a slice from the surface, the amounts are usually high. If however, the determinations are made on center slices of ham, for instance, the amounts are much lower. It is reasonable to expect more nitrite in the surface of cured meat than in the deeper layers. Samples of cured meats for analysis should be kept cold between the time of sampling and analysis, else there will be a great change in the nitrite situation. Cooking in the home also reduces the quantity of nitrites in meat. This probably justifies a more liberal standard for nitrite content.

Not much work has been done on the effect of curing solutions on pathogenic bacteria, which may be present in the meat. The most direct method, but one susceptible to experimental difficulties would involve the use of meat either naturally or artificially infected. Results of such an experiment with pork from animals artificially infected with swine fever were

reported by Zeller and Beller.¹⁸³ Pork cured in brine (25%) for 22 to 181 days caused the disease in 12 out of 15 tests (80%). In a second series with the meat of infected pigs preserved in dry salt for periods varying from 22 to 315 days, feeding caused swine fever in 11 out of 13 experiments. When pieces of large intestine were preserved in dry salt for 22 to 164 days, 10 out of 13 sound pigs fed, developed swine fever. Similar experiments with dry salted small intestine set up infection in 10 (one animal recovered) out of 14 tests. The brine solution itself was less infective, for when fed to pigs, only two out of 11 succumbed to swine fever. Seventeen experiments with infected pigs' livers, kept for various periods in a frozen condition, yielded negative results in six cases, infection with death in nine, while two were doubtful. The two experiments, which lasted as long as 196 and 226 days, caused no infection on feeding, suggesting that the virus dies out in time under these conditions. *Salmonella schottmülleri* and *Salmonella enteritidis*, in Wieser's¹⁴ experiments were killed in a month or two in 20 to 25 per cent solutions of salt but survived and even multiplied in meat. Henniger¹⁸⁴ reached about the same conclusions.

Brooks *et al.*¹⁸⁵ found that in bacon satisfactory color and flavor is compatible with low nitrite content. The characteristic flavor of bacon is due primarily to action of nitrite on the flesh and satisfactory bacon can be made with salt and nitrite only. Presence of nitrate or microbial action during pickling and maturation is not essential for the development of bacon flavor. These investigators believed that use of nitrite in curing would permit the following changes in commercial practice: (1) greater control of the concentration of nitrite in the curing solution; (2) greater latitude in the composition of tank curing solutions; (3) a reduction in the microbial population on the surface and consequently a better keeping bacon.

Two extensive investigations have been carried out in the author's laboratory. Tanner and Evans¹⁸⁶ used different amounts of sodium nitrate with three different anaerobic bacteria, *Clostridium botulinum*, types A and B, *Clostridium putrificum*, and *Clostridium sporogenes*. Determination of concentrations of sodium nitrate by analysis showed irregular inhibition of seven strains of *Clostridium botulinum*.

Sodium nitrate was not found to be as good a preservative as sodium nitrite by DeBoer and Tanner.¹⁸⁷ Sodium nitrate had no effect on *Clostridium botulinum*. Even amounts as high as three per cent were without effect. When the meat samples were stored at 3.3°C. (38°F.), the temperature used in curing cellars, nitrite formation from nitrates took place slowly in concentrations of nitrate below one per cent. Above this amount sufficient nitrite is formed to materially inhibit bacterial development.

Jensen and Hess¹⁸⁸ studied the effect of sodium nitrate on *Clostridium sporogenes* in a spiced-ham medium. About 50 spores were inoculated into

each tube. Growth appeared in 72 hours in the tubes with no nitrate and in the tubes containing .02 per cent. After 76 hours all tubes excepting the ones containing .5 per cent and 1.0 per cent of sodium nitrate showed active growth. No growth appeared in the tubes containing .5 and 1.0 per cent of nitrate after four weeks' incubation. This experiment was carried out with a very small inoculum and no evidence was given as to whether the spores were killed or whether they were merely inhibited.

Effect of Heat on Bacterial Spores in the Presence of Nitrate. It has been suggested that spores of *Clostridium botulinum* might be destroyed by heat in the presence of sodium nitrate. Jensen heated tubes to which 25 spores of *Clostridium botulinum* and various amounts of nitrate had been added at 68.3°C.(155°F.) for five hours. They were not injured nor were the results any different when 1,000 spores were added to the tubes. When the heating was carried out at 80°C.(176°F.) for four hours, some heat injury was apparent. Heating at 93.3°C.(200°F.), a higher temperature than is used in processing chopped ham, showed great injury to spores in presence of one per cent of nitrate. From these results Jensen speculated that in the presence of nitrate, nitrite, and salt spores of *Clostridium botulinum* and *Clostridium sporogenes* might be killed at much lower temperatures than called for in standard canning practice. More convincing results on this question were reported by Yesair and Cameron.¹⁸⁹ Introduction of .1 per cent of sodium nitrate, .005 per cent of sodium nitrite, or two per cent of salt caused greater than 70 per cent reduction in spores.

While admitting that results from laboratory and culture tube experiments are valuable, Jensen and Hess¹⁸⁸ carried out experiments using meat and a strain of *Clostridium sporogenes* which was said to have characteristics of *Clostridium botulinum* with exception of toxin formation. Pork trimmings in batches of 400 pounds were used. These were chopped and divided into two batches of 200 pounds each. One lot was cured with the regular curing ingredients for spiced ham: two per cent sucrose, 3.5 per cent salt, four ounces sodium nitrate, one-half ounce sodium nitrite and one ounce of mixed spice. The other lot of 200 pounds was cured with the same mixture except that sodium nitrate was omitted. To each lot during mixing a suspension of spores of *Clostridium sporogenes* was added so that each six-pound can would contain 10,000 spores. Samples for examination were taken during the experiment. All of the six-pound cans were placed at 37.2°C.(99°F.) for 30 days and then opened for inspection. The meat cured without nitrate but containing nitrite was sound and no can swelled in 30 days. The meat cured with nitrate and nitrite showed gas formation to some extent. Three of the 32 cans swelled, showing that nitrate was conducive to gas formation as Jensen has shown in other publications.

The experiment was repeated using nitrite alone in one batch and nitrate and nitrite in the other. Of 32 cans of meat cured with nitrite alone, 19 became putrid, nine were sound, and four were soft swells with proteolysis and fermentation. Jensen believed that these results showed

189. Yesair and Cameron. 1942. The Canner, 94. Conv. Number, 89-92.

the value of nitrate in inhibiting putrefactive anaerobes. The inhibition was not complete, however. Jensen and Hess reported that nitrate is reduced to hydroxylamine in a nitrate-nitrite-salt-sugar curing mixture. They further believed that this incubated catalase permitted formation of hydrogen peroxide which killed *Clostridium sporogenes*. Using quite different technic DeBoer and Tanner¹⁸⁷ found no effect of sodium nitrate on thermal death time of *Clostridium botulinum* in concentrations of 200 to 400 p.p.m.

Effect of Sodium Nitrite on Bacteria. Nitrites of sodium and potassium have an important role in imparting a desired red color to cured meats. Food-control officials have rightfully regulated composition of curing solutions to prevent addition of unnecessarily large amounts of certain constituents which might injure the health of consumers. Nitrites were added to meat-curing solutions as color fixatives. When nitrates are used, it is assumed that they are reduced to nitrites. During late years, evidence has been accumulating to indicate that nitrites may function to some extent as preservatives.

Use of nitrite in place of nitrate in the curing of meat arose from an observation made by Polenske¹⁷³ that nitrite was present in old nitrate curing solution. He believed that reduction of nitrate to nitrite was accomplished by bacterial activity. Nothwang¹⁷⁴ made the same observation, but added that reduction might be due to the meat tissue itself. In light of Bernheim and Dixon's work,¹⁷⁰ Polenske's explanation is more probable. Bernheim and Dixon found that muscular tissue from a considerable number of animals including the ox and the pig was completely without power to reduce nitrate to nitrite. Lehmann¹⁶⁷ and Kiskalt,¹⁷⁷ working separately, found that red color of cured meat was due to nitrite and not to nitrate. Lehmann boiled fresh meat with nitrite in a weak acid solution and secured a product having the red color of cured meat. When treated with sodium nitrate, this red color did not appear. Kiskalt found, in addition, that if meat were allowed to stand several days in contact with nitrate, a red color would result. Haldane¹⁷⁹ proved that the color of meat cured with nitrate and nitrite was due to nitric-oxide-hemoglobin which was formed by the action of nitrous oxide on hemoglobin. He also found that the permanent pink color of boiled cured meat was due to a water insoluble compound which proved to be nitric oxide-hemochromogen. Hoagland¹⁸⁰ repeated Haldane's experiments and obtained the nitric oxide-hemoglobin as the red colored element of cured meat. He concluded that neither nitrates nor nitrites, as such, had any influence in preserving the color of fresh meat. The brown color of meat cured with excessive nitrate was thought to be due to the action of sodium nitrite on hemoglobin. An interesting observation was made by Klut,¹⁹⁰ who noted that some waters would change the color of beef to a lighter or deeper red on boiling. Experiments showed that very small amounts of nitrite were sufficient to cause change in color. Nitrate containing waters might give the color if they were allowed to remain in contact with zinc, for the metal acted as a

reducing agent in this case and the nitrite so produced would cause the change in color.

After it had been shown that the active agent in color fixation was nitrite and not nitrate, efforts were made to use the former in curing solutions. Among the first to recommend it was Glage¹⁹¹ who proposed the use of partially reduced nitrate prepared by heating dry saltpeter in a kettle. This procedure, of course, led to a product of unknown nitrate-nitrite composition which, when used in the curing of meat, gave somewhat irregular results. From this time on, however, commercial preserving salts containing nitrite appeared on the market. Auerback and Riess¹⁹² found that meat cured with nitrite contained more of this salt than meat cured with nitrate. They found that meat exposed to action of an ordinary curing solution containing five per cent potassium nitrate for several weeks contained, at the most, a few milligrams of nitrite per 100 grams of meat. Amounts exceeding 10 milligrams per 100 grams were found only in the surface portions. Curing solutions which contained a large amount of sodium nitrite caused it to penetrate uniformly into the meat. Ten to 40 milligrams per 100 grams were found in surface samples. Auerback and Riess believed that amounts of sodium nitrite exceeding 15 milligrams per 100 grams indicated that a nitrite cure had been used. Pollak¹⁹³ found that a nitrite cure was practical. The amount of nitrite in the finished product was even smaller than usually found in meat cured with nitrate. Careful control was required in order to obtain good results. Experimental work on a commercial scale by Lewis, Vose, and Lowery¹⁹⁴ demonstrated that a nitrite cure, when properly carried out, yielded a product equal, or superior, to that resulting from a nitrate cure. The amount of sodium nitrite found to be most satisfactory was one-tenth the amount of sodium nitrate usually used. The resulting product contained no more, and often less, nitrite than when the customary amount of saltpeter was used. These conclusions were, in general, concurred in by Kerr, Marsh, Schroeder, and Boyer.¹⁹⁵

The results of this investigation were confirmed by Riess, Meyer, and Müller¹⁷² who compared the effects of curing solutions containing nitrite with those containing nitrate. They found that meat cured with nitrite never contained more than 10 mg. of sodium nitrite per 100 grams and frequently only a fraction of a milligram was found. They also pointed out that meat cured with two per cent saltpeter¹⁹⁶ contained, in addition to the traces of sodium nitrite, 100 to 150 mg. of saltpeter. The possibility exists that this saltpeter may be transformed suddenly under uncontrolled conditions into nitrite. They recommended, as a result of their experiments, a salt mixture containing not more than .6 per cent sodium nitrite with sodium chloride. When this mixture was stored in dry rooms, very little

196. Saltpeter, according to Reiss, Meyer, and Müller, refers to a mixture of sodium and potassium nitrates.

destruction of nitrite occurred, but when it was placed in wet rooms, appreciable loss took place in a short time. Riess, Meyer, and Müller found that the advantages of use of .6 per cent sodium nitrite curing mixtures were as follows: (1) a curing time of one-half to one-third that usually necessary with saltpeter; (2) thorough reddening of meat and thorough salt penetration proceeded faster when this cure was used; (3) nitrite content of the finished product was no larger and was frequently smaller than that receiving a nitrate cure; (4) appearance, odor, flavor, and keeping quality of such products were equal to, or superior to, those cured with saltpeter.

The equivalence of sodium nitrate to sodium nitrite in meat curing has been stated to be 10 to 1 by Lewis and Moran¹⁹⁶; others have stated it to be 5 to 1 and lower. An exact equivalence which will hold under all conditions is probably not possible since the conditions which obtain in each separate experiment will greatly affect the results. Assuming that nitrites are somewhat germicidal, the number of nitrate-reducing bacteria influence the results. If nitrate reduction is slow, there will be less effective nitrite. At the Iowa Agricultural Experiment Station,¹⁹⁷ nitrites proved effective in a concentration of 1/10 to 1/20 that of nitrates generally used. A desirable color was not produced until the concentration of salt was at least 10 per cent. It is quite well established that constant equivalence values do not exist, for the amount of nitrite resulting from bacterial reduction of nitrate would depend upon many different factors: type, numbers and activities of microorganisms, physical conditions which obtain in the curing solution, time of curing, etc.

Another factor of importance is that constant relationships do not seem to exist between the amount of ingredients in curing solutions and their incidence in cured meats. This seems to be borne out by data in publications of Kerr, Marsh, Schroeder, and Boyer¹⁹⁵ and others. This would seem to indicate, therefore, that it might be better to control amounts of nitrate and nitrite in the finished product than in the curing solution.

Saltpeter (sodium nitrate) has had the longest use in meat-curing solutions. Since nitrates must be reduced to nitrites, packers desired to use nitrites as such to avoid the dangers which might result from inadequate conversion of nitrates to nitrites. Losses from uneven or inadequate fixation of color were not uncommon. Since many bacteria exist which may reduce nitrites, it is necessary either to add sufficient to fix color before it is used up or to have a constant source supply (nitrates). The nitrate cure permitted this but the nitrite cure introduced the hazard of nitrite disappearance. Consequently, there may be much merit in the mixed cure in which both nitrates and nitrites are added. The nitrates may act as a reservoir for replacement of lost nitrite.

Regulation of the amounts of these salts used in meat-curing solutions rests in the United States with the Bureau of Animal Industry and the bureau has rightfully been diligent to prohibit the use of unnecessarily

197. Iowa Agr. Expt. Sta., Ann. Rpt. 1926, 28-29.

large amounts. Too little is known, however, about the toxicity of nitrites in cured meat products.

The conditions caused by the first World War made it necessary for the Secretary of the United States Department of Agriculture¹⁹⁸ to revise regulations to permit the immediate use of sodium nitrate (Chile saltpeter) in place of potassium nitrate for curing of meat in establishments where federal inspection is maintained. This salt has been used since then in spite of the fact that many packers claim that better results are secured with potassium nitrate. In 1922 the United States Department of Agriculture¹⁹⁹ amended the rules to permit, among other things, saltpeter and nitrate of soda.

Amendment 4 to B.A.I. Order 211, revised, issued October 19, 1925²⁰⁰ permitted the use of saltpeter, nitrate of soda, and nitrite of soda. This was indeed a mixed cure and a distinct departure from former practice. The bureau stated that meats could be successfully cured with quantities of sodium nitrite that would not result in the presence of more than 200 parts per million in the finished meats. It was stated that, in general, the correct quantity of nitrite is approximately one-tenth that of nitrate. The substitution of one pound of nitrite for each 10 pounds of nitrate was recommended. The basis for this ratio (10 to 1) is hard to determine.

After use of excessive amounts of sodium nitrate in pumping pickle was observed by the Bureau of Animal Industry in 1926,²⁰¹ a warning was issued that amounts of saltpeter or sodium nitrate over one per cent would be held excessive in pumping pickle.

Immediately after release of these rulings, the bureau began to record itself in favor of a nitrite cure as the approved cure for comminuted meats and sausage. It was suggested that the use of nitrate be eliminated when as much as one-quarter ounce of sodium nitrite is used per 100 pounds of meat. This opinion was based on the observations that satisfactory cured meat could be made with such a cure.

Although many meat packers favored the nitrite cure, others believed that a mixed cure containing both nitrate and nitrite, was more satisfactory. It was suggested that, although nitrites made cured meats red, a little residual nitrate would be desirable to act as a constant source of nitrites. Accordingly, in the fall of 1931, the chief of the Bureau of Animal Industry issued a statement permitting one-quarter ounce of nitrite, and two and three-quarter ounces of nitrate per 100 pounds of meat in curing solutions. The arguments in favor of such mixed cures were several. The most important was that satisfactory cured meats had been prepared for years with a mixed cure and to change abruptly to the nitrite-cure would change the properties of the final products from those packing plants which had worked out a satisfactory procedure. Furthermore, it would be unnecessary to rely absolutely on the activities of nitrate reducing bacteria.

198. U. S. Dept. Agr. Bur. Anim. Indus., Service and Regulatory Announcements, January, 1925.

199. Idem Reg. 18, Sec. 6, Par. 2, B.A.I. Order 211 (1922).

200. Idem, October, 1925.

201. Idem January, 1926.

The amount of nitrite in cured meats naturally varies with the product and the method used for curing it. Moulton²⁰² has summarized the knowledge on this question. Lewis and Vose²⁰³ reported from 42 to 53 parts per million of nitrite in a ham which had received a regular nitrate cure. Jones²⁰⁴ reported 72 to 960 parts per million of nitrite in American ham. In his published article the methods of sampling, analysis, and manipulation of the samples were not given. The amounts which would be secured would depend largely on type of sample and its treatment after collection.

The ruling of the B.A.I. that the finished product contain less than 200 parts per million is in many respects meaningless. Nothing was said as to how or when the samples were to be taken. It is apparent that a surface sample of a ham recently removed from a curing solution with 600 or 700 p.p.m. of nitrite would show nitrite content considerably in excess of 200 p.p.m. On the other hand, a sample from a deeply seated area in the ham would show a nitrite content well within the limits of 200 p.p.m. Unless the method of sampling is specified, a ruling such as the one under discussion can but lead to confusion. A standard such as that just mentioned is meaningless unless standard procedures or methods are used in its enforcement.

Another very serious element for error is the technic used for preparation and handling of the sample. If the samples are not properly prepared and analyzed immediately, nitrate and nitrite data will be inaccurate. Bacteria may reduce nitrates and yield very high nitrite results, or, on the other hand, they may decompose the nitrites giving lower data than should be expected. Samples for the determination of nitrates must be analyzed promptly or stored under adequate refrigeration only for very short periods of time.

In some products such as spiced luncheon loaf in tin cans, the nitrite content decreases rapidly during storage, the rate of disappearance depending on the temperature of storage and probably the numbers and activity of the bacteria present. Ruyle and Tanner,²⁰⁵ in an examination of commercial canned meats, did not find curing salts in sufficiently high concentration to prevent development of common anaerobes. After storage for several months the nitrite content in many cans is zero and almost so in the majority. Cooking, as carried out in the home, also destroys nitrite in cured meats. Results of experiments have shown that boiling and frying frequently destroys all of the nitrites, not even a trace showing on analysis even with products which have received a commercial nitrite or nitrate cure.

Nitrates are readily reduced to nitrites by many different chemical substances and microorganisms. In the preservation of meats with curing solutions containing nitrate only, it is well known that it must be reduced to nitrite before the color may be fixed.

Bacteria are known to be active in reducing nitrates and probably play the most important role in this respect in meat-curing solutions containing nitrates. The subject has been studied mainly from the standpoint of agriculture and methods for determining the reduction with pure cultures. Maassen¹⁷⁵ studied the process with over 100 species of microorganisms in peptone broth containing five per cent of potassium nitrate. Eighty-five of these species formed large amounts of nitrites. Maassen stated that the amount of potassium nitrate used hindered the growth of some of the bacteria. He also stated that some of them were hindered by the nitrite formed showing that it has a detrimental effect on bacteria. Results of investigations by many others have shown the importance of bacteria as nitrate-reducers.

It is possible that the meat itself may also reduce nitrates. Abelous and Gerard²⁰⁶ reported results of an investigation which seemed to indicate the presence of an enzyme in horse flesh which reduced nitrates. Their conclusions have been criticized, however, on the basis that they did not work with sterile extracts and the reduction they attributed to the enzyme may have been brought about by microorganisms. Bernheim and Dixon¹⁷⁰ obtained just the opposite results. Horovitz-Vlasova²⁰⁷ reported *Bacillus halobicus*, an obligate halophilic organism which reduces nitrates to nitrites and then to free nitrogen. Zobell²⁰⁸ showed that many bacteria could reduce nitrates to nitrites. The latter, in turn, were also reducible. Stickland²⁰⁹ reported nitrate reduction by *Escherichia coli*.

Nitrites may also be decomposed by bacteria and some of the loss in nitrite must be attributed to microorganisms.

Inhibition of growth of bacteria by sodium nitrite is dependent upon the pH of the substrate, according to Tarr.²¹⁰ At pH 6, he found .02 per cent of sodium nitrite to entirely inhibit or strongly retard growth, while at pH 7 little or no inhibition was observed. A marked variation in susceptibility of different bacteria to nitrite was observed. Bittenbender, Degering, Tetrault, Feasley, and Gwynn,²¹¹ using *Staphylococcus aureus* and *Escherichia coli*, found no destruction of these organisms by 30.8 per cent solutions in 10 minutes at pH 3 to 8. In view of such results as these, Tarr believed that sodium nitrite may be a bacteriostat rather than a bactericide.

DeBoer and Tanner¹⁸⁷ also found sodium nitrite to possess marked inhibitory action on microorganisms in meat held at 3.3°C.(38°F.). Amounts as low as .2 per cent not only preserved meat but actually reduced the number of bacteria. The bacterial flora in meat with nitrite became simpler, finally consisting mainly of small rods without spores. Tanner and Evans²¹² several years before had also found sodium nitrite to be bac-

tericidal. Acidity is an important factor. Variations in pH may explain different results secured by investigators under various conditions. Tarr²¹³ made similar observations. Whether sodium nitrite will inhibit *Clostridium botulinum* seems to depend on several factors among which the number of cells appears to be most important. With heavy inoculations, probably much heavier than those which would be encountered in actual practice, the amounts of sodium nitrite permitted would probably not be of any value. With light inoculations with few spores of *Clostridium botulinum*, the results are different.

PHARMACOLOGY OF NITRITES

The chemical properties of sodium and potassium nitrite made the pharmacology of these salts of importance in meat preservation. Most of the evidence in literature, however, involves ingestion of far larger amounts of nitrite than are used in meat curing and certainly larger amounts than would be found in cooked cured meats as they would be prepared for the table. There seems to be no evidence to indicate that the amounts of nitrite ordinarily found in cured meats are harmful.

Since sodium nitrite and nitrate have been added to meat curing solutions, many investigators have suggested that these salts might have a detrimental effect on the health of human beings. Important among the reports which have been published are those by Grindley and MacNeal.²¹⁴ Physiologically nitrites are very active, and they reached the conclusion that their poisonous action in large doses was due to two factors. The first was the effect on the blood. They found that animals poisoned with nitrite had had a large part of the blood oxyhemoglobin changed to methemoglobin. The second factor was the direct effect on the tissues. The nature of this action was not definitely known, but Grindley and MacNeal believed that it was direct tissue asphyxia. Nitrites have been found to be toxic for all animals examined, both hemoglobin containing and non-hemoglobin containing. This includes insects, arachnidae, protozoa, infusoria and mammals. Many plants were also injured by nitrites.

Riess, Meyer, and Müller¹⁷² gave, as an introduction to their paper, a brief history of the use of nitrite in meat curing in Germany. Since 1916 it had been forbidden in the industrial preparation of meat products. The dangerous properties of the salt were demonstrated by the dosages regarded as permissible in medical practice. The German pharmacopoeia gave, as the largest single dose for an adult man, .3 gram and as the largest daily dose one gram. The Swiss pharmacopoeia gave as the corresponding doses .1 and .3 gram. Doses of .2 to .3 gram can produce humming in the ears, vertigo, sensitivity to light, nausea, cyanosis, and irregularity in heart action. The literature was found to contain records of severe illness caused by .3 to .6 gram. It was considered in Germany that any material that affected the health of men in amounts of less than one gram should be used with greatest care. However, they found by experiment that a carefully

213. Tarr. 1942. J. Fish. Res. Bd., Canada 6.

214. Grindley and MacNeal. 1917. Studies in Nutrition, Univ. of Ill., 1917

controlled curing process made possible the use of nitrite in the preparation of cured meats without the resulting product containing this substance in quantities sufficient to be detrimental to health. Riess, Meyer, and Müller's experimental work seemed to be complete. They found that substitution of nitrate with nitrite decreased the curing time by one-third. Addition of .6 per cent of nitrite to common salt was sufficient when using 80 grams of salt for 1,000 grams of meat.

There are few data on the reaction of the salts of nitrous acid on bacteria, but one would suspect that a substance affecting so many other types of living things might have some influence on such small organisms as bacteria. Lewis and Moran¹⁶⁶ found this to be the case. Their experiment included determinations of the effect of nitrite alone and also the effect of combinations of nitrite with sodium chloride. They found that .2 per cent of sodium nitrite, the lowest concentration used in their work, completely inhibited proteolysis in cultures of *Clostridium putrefaciens*. In another experiment using concentrations of .01 to .05 per cent, they observed no inhibition at any concentration below .05 per cent. Apparently, the effective concentration lies between .05 and .2 per cent sodium nitrite. An experiment was also conducted with beef round covered with a solution containing nitrite, nitrate, or chloride. The nitrite solutions contained .03, .06, .09, .12, and 18 per cent of sodium nitrite. After nine days, growth and putrefaction were present in all the vessels containing nitrate and salt of concentrations 10 times that of the nitrite. The nitrite-beef combinations showed no evidence of spoilage even after 21 days. This would seem to indicate that nitrite is very effective in inhibiting bacterial growth even in very low concentrations. The actual amount of effective nitrite must have been lower than the percentage concentrations appearing in the tables, for the amount of meat added was not considered in the calculations. The effect of nitrite, according to these data, must be different for *Clostridium putrefaciens* than for the ordinary meat flora. Whether inhibition of bacteria would be noticeable in the curing cellar is another matter.

The experiment on the effect of combinations of sodium nitrite and sodium chloride was performed with *Clostridium sporogenes* as the test organism. Proteolysis for the 48-hour period was inhibited at .05 per cent sodium nitrite in all the salt concentrations from one to five per cent. However, for the seven- to 14-day period, proteolysis was observed in all nitrite concentrations from zero to .2 per cent (the highest sodium nitrite concentration used) in all the tubes containing zero to two per cent salt. In other words, after two weeks' incubation, growth had appeared over the entire range in the tubes containing nitrite only. Proteolysis was checked in nitrite concentrations at and above .05 per cent in salt concentrations of three to five per cent. In another similar experiment, these authors found that concentrations of .05 per cent and above prevented proteolysis in the absence of salt for the same incubation period. The difference between the effective concentration for these two experiments is the difference between .05 per cent and .2 per cent or .15 per cent.

Some attention has been given to the formation of nitrites from nitrates in the intestines and the possible evil effects of the former. Barth,²¹⁵ in 1879, studied the effect of Chile saltpeter on animals which had accidentally ingested it. Symptoms of illness resulted including weakness, unconsciousness, muscle twitchings, etc. Barth attributed the symptoms to nitrites formed from the nitrates, an opinion which was not generally accepted by toxicologists. Binz and Gerlinger²¹⁶ confirmed Barth's work and believed that nitrite poisoning occurred. The experiments just reported leave the situation in an unsatisfactory state. Clear-cut conclusions cannot be reached on the toxicity of nitrites in foods. It is evident, also, that the amounts of nitrite used in the above experiments were considerably greater than would be found in cured meats.

A comprehensive investigation of the effect of saltpeter in the diet was carried out at the University of Illinois in 1907 and 1908.²¹⁴ Twenty-four subjects were used in these experiments. The results of this investigation indicated that potassium nitrate as used in meat-curing solutions showed no effect on the subjects. Mathews,²¹⁴ who studied the pharmacology of nitrates and nitrites in this investigation, stated that the potassium in the potassium nitrate could be disregarded when the nitrate was taken in such small doses as those given in the experiments. The nitrate ion, in itself, was said to possess about the same physiological power as the chlorine ion. Sodium nitrate as such was said to have the same action on metabolism and nearly all tissues of the body as sodium chloride.

The situation for sodium nitrite is apparently different. Mathews quoted a number of cases of illness following ingestion of nitrites but the amounts were usually greatly in excess of those used in curing solutions. Data from injection experiments are not pertinent to this discussion.

Tarr²¹³ observed that addition of sodium nitrite to the diet of cats on the basis of an average-size man consuming one pound of fish containing .2 per cent of this salt daily for six days did not affect growth or development of internal organs.

Effect of Heat on Nitrite Content of Cured Meats. Heat used in cooking destroys nitrite in meat. Cooking should probably not be relied on to destroy large quantities of nitrite. Brooks and his colleagues¹⁸⁵ observed that other factors than concentration of nitrite in cured meat influenced nitrite destruction during heating. Roughly the time required for 50 per cent destruction increased with the initial concentration, ranging from 13 to 120 minutes for values of 30 to 589 grams of sodium nitrite per 10⁶ grams of tissue. From these results, the authors claimed that reduction from a high to a low content of nitrite could not be expected. With amounts of nitrite not over 200 p.p.m. reduction was probably significant. DeBoer and Tanner also observed destruction of sodium nitrites in meat by heating.

Effect of Mixed Curing Solutions on Bacteria. Meat-curing solutions contain salt, saltpeter, sodium nitrite, and sugar and, in addition, various

215. Barth. 1879. Inaug. Dissert., Bonn.

216. Binz and Gerlinger. 1901. Arch. f. Internatl. Pharmacodyn. et Thér. 9, 441-450.

substances which are extracted from the meat. While much work has been done on the effect of the single ingredients on microorganisms, it is a question how far the conclusions may be used for inferring what the effect would be in combination with the other ingredients. Mixed curing solutions probably developed from salt solutions and vary greatly in composition. Evans and Tanner²¹⁷ stated that commercial curing solutions were effective in preventing growth and toxin formation when the proportions of curing mixture used in their experiments were such that the critical concentrations of sodium chloride were approximated.

Administrative Regulations Concerning Use of Sodium Nitrate and Sodium Nitrite in Meat Products (De Boer and Tanner¹⁸⁷). In the United States, regulation of the amounts of nitrates and nitrites used in meat curing originates from the Bureau of Animal Industry of the United States Department of Agriculture. In January, 1925, a ruling was issued that sodium nitrite could be used in curing solutions but that the cured product must not contain more than 200 p.p.m. of nitrite, since meat given a nitrite cure has been found to be higher in nitrites than when cured with nitrates alone. In 1931, the Bureau of Animal Industry ruled that "mixed curing solutions" containing both nitrate and nitrite, shall contain not more than one-quarter ounce of nitrite or two and three-quarter ounces of nitrate per 100 pounds of meat. A prior ruling had fixed the amount of nitrate in straight nitrate curing solutions as three ounces per 100 pounds.

The Canadian Government (1941) regulation in regard to the use of nitrates and nitrites in meat curing are similar to those of the United States. Both nitrates and nitrites may be used and no limits are placed on the amounts to be used in curing, but the finished product shall not contain more than 200 p.p.m. of nitrites. The supervision rests with the Veterinary Director General in the Department of Agriculture.

In Great Britain the use of saltpeter in conjunction with common salt is permitted. However, a provisional regulation dated October 20, 1939, (1940) made by the Minister of Health, makes the addition of sodium or potassium nitrite to bacon and hams now permissible. On April 30, 1940, this provisional regulation was amended as follows: "No person shall manufacture for sale or sell any cooked cured meat intended for human consumption other than bacon or ham, which contains sodium or potassium nitrite in proportions exceeding 200 parts per million calculated as sodium nitrite."

German regulations (1936) permit the use of salt-sodium nitrite pickling compound for certain meats, containing between .5 and .6 per cent of sodium nitrite. Use of saltpeter simultaneously with a nitrite and sodium chloride mixture is prohibited. However, for large cuts of meat saltpeter may be used together with a mixture of nitrite and sodium chloride provided not more than one kilogram of it is present for every 100 kilograms of the nitrite-sodium chloride mixture. Recently, suggestions have been made for the establishment of a legal maximum amount of

217. Evans and Tanner. 1934. *Zentbl. f. Bakt.*, Pt. 2, 91, 135-147.

nitrate in order to keep the maximum amount of nitrite formed within the limits set by the Act of 1934.

France permits the use of saltpeter in meat curing but regulations specify that nitrites cannot be used (1936).

Swiss regulations (1936) are similar to those of Germany. A salt-nitrite mixture colored by spices, such as mace and paprika, is specified. This mixture shall not contain more than .6 per cent of the weight of the salt as sodium nitrite and cannot be sold in quantities less than 25 kilograms and then only by official establishment (1932).

Italian regulations specify that saltpeter may be present together with sodium chloride for curing purposes to the extent of .25 grams per 1,000 grams of salt (NaCl) (1932).

Spain does not permit the use of saltpeter or the nitrites of sodium and potassium in meat-curing solutions (1932).

Sweden and Norway have no state regulations governing the use of curing salts. Any authority exercised regarding food handling rests with local authorities. However, most of them permit the use of saltpeter in meat curing (1932).

Danish regulations specify that in meat and meat products produced for export only sodium chloride, sodium or potassium nitrate mixtures, and sugar are to be used (1932).

In the Netherlands saltpeter may be used but nitrites are not permitted in meat curing (1932).

Belgium permits the use of sodium and potassium nitrate in amounts sufficient to form the red color in cured meat (1932).

Austria does not permit the use of saltpeter and nitrites of sodium and potassium in meat. Only sodium chloride can be used (1932).

In Czechoslovakia no specific regulations exist regarding the use of saltpeter in meat curing; however, the use of any preservative harmful or injurious to health is prohibited (1932).

Romania permits the use of salt and saltpeter in the preservation and curing of meat (1932).

Bulgaria also permits saltpeter and salt in meat curing (1932).

In Poland saltpeter can be used alone and in combination with sodium chloride to the extent of 300 milligrams of saltpeter for 100 grams of meat or meat products (1932).

In Hungary 2,000 milligrams of nitrate are permitted to be used per kilogram of meat. The amount of nitrate in sausage shall not exceed 250 milligrams per kilogram (1932).

In Argentina (1941) the use of both nitrates and nitrites is subject to governmental regulation. *Nitrate*: The brine that is used to prepare meats, hams, etc., cannot contain more than one-hundredth part of sodium or potassium nitrate in relation to the percentage of sodium chloride used. *Nitrite*: It is permissible to add sodium nitrite to meats or preserved meats in quantities which do not exceed 150 to one million parts, or a proportion equivalent to fifteen-thousandths per cent (.015 per cent), provided that it does not contain impurities which could alter the product.

As mentioned elsewhere in this chapter, such regulations are difficult to interpret since they do not stipulate how the samples shall be taken. Definite methods of sampling ought to be stated. The amount of nitrite used should be only that required for production of good-quality cured meat. Excessive amounts in the curing solution would increase the cost of meat curing.

Microbiology of Curing Solutions. Results of comprehensive investigations on this subject have not been published. Not much is known about the numbers of bacteria which may be present or the species which result from the selective action of the curing agents. The latter are mainly species which can endure salt or need it. Sturges²¹⁸ and Heideman²¹⁸ believed that, for this work, the situation would be clearer if they grouped the organisms according to salt relations, disregarding for the time being their morphological characteristics. With this in mind, the following scheme was proposed:

HALOPHILIC ORGANISMS

Organisms which grow on media containing 12 per cent NaCl.

GROUP I. SALT OBLIGATE

Organisms requiring for growth salt in concentrations greater than one per cent.

GROUP II. SALT PREFERENTIAL

Organisms which grow more luxuriantly in media containing more than one per cent salt than on standard media and usually exhibiting extreme irregularities on the latter.

GROUP III. SALT FACULTATIVE

Organisms which grow with equal luxuriance on standard and on 12 per cent NaCl media.

GROUP IV. SALT TOLERANT

Organisms which grow on 12 per cent media (often exhibiting irregular forms) but grow more luxuriantly on standard media.

The brines or curing solutions used by Heideman usually contained about 15 per cent of salt, a few per cent of sugar and a little nitrate. Five organisms were studied. He found that sugars were necessary for the formation of "rope," as well as a proper hydrogen-ion concentration. Sturges has shown that old brine in which hams are being cured contains many bacteria of varied property and function. He isolated 100 cultures which showed very diverse characteristics.

The medium used has great influence on the results which are secured in plating curing solutions. Haines²¹⁹ secured the greatest number of colonies on salt-pork agar. He found that salt was also necessary in all diluting fluids else from 50 to 90 per cent of the flora did not develop. Twenty per cent of salt in these solutions was most suitable. Wide diversity of types was reported. Horowitz²²⁰ also found the salt concentration in the curing solution to be important. He isolated bacteria which could reduce nitrates to nitrites but this ability became less and less as concentration of

218. Sturges. 1923. *Abs. Bact.* 8, 14; Heideman. *Idem* 8, 14.

219. Haines. 1939. (*Gt. Brit.*) *Food Invest. Bd., Ann. Rpt. for 1938*, p. 75.

220. Horowitz. 1931. *Ztschr. f. Untersuch. der Nahr. u. Genussmtl.* 62, 596.

salt increased. From old curing solutions an organism was finally isolated which reduced nitrates to nitrites with formation of gas. Without presence of salt it would not develop at all. Besides this organism two other types were found. One produced acetyl-methyl-carbinol while the other was lipolytic. The former were aerobic, sporeforming bacteria of *Bacillus subtilis* type. In curing solutions acetyl-methyl-carbinol is formed from sugar in the curing solution and also from glycogen in meat muscle. The lipolytic type was a coccus named *Micrococcus lipolyticus*. This organism caused spoilage in bacon and other fat-containing meat products. Its activity was stopped by keeping the temperature below 5°C.(41°F.). Another nitrate-reducing organism, or the same one described above, was named *Bacillus halobicus* by Horovitz-Vlasova.²⁰⁷ It formed gas in curing solutions and was described as an obligate halophilic organism which reduced nitrates to nitrites and nitrogen.

Brooks *et al.*,¹⁸⁵ on bacteriological analysis of curing solutions from tanks in which bacon was being cured, reported the "total" or direct microscope count of bacterial cells to be very high, of the order of 10^7 to 10^8 per ml. The proportion of this flora viable on laboratory media was greatly influenced by the technic adopted. When media containing salt are used, more viable bacteria are revealed. It was difficult for Brooks and his colleagues to present their results. Commercial curing solutions were said to contain a viable flora, 10 per cent of which is viable on "ordinary" media and 90 per cent is viable as special flora on "special" media.

"Ropy" Curing Solutions. This abnormality of curing solutions is caused by encapsulated bacteria which also cause "rope" in other foods. Heideman²¹⁸ isolated five organisms which produced ropiness in curing solutions. They grew best at pH 8 and very little below pH 6. Another bacterium causing this defect was named *Micrococcus lipolyticus* by Horovitz-Vlasova²⁰⁷; it resembled *Micrococcus albus* and *Micrococcus flavus-liquefaciens*.

Gas Formation in Canned Cured Meat Products. Canned cured meats, ham, spiced ham, and a few other comminuted products, are subject to deterioration accompanied by gas formation. Jensen, Wood, and Jansen²²¹ and Jensen and Hess²²² have traced this spoilage to members of the genus *Bacillus* although these organisms are considered to be nongas-formers from carbohydrates. Consequently, formation of large amounts of carbon dioxide in sugar-cured meat products at temperatures from 23.9 to 48.9°C. (75 to 120°F.) presented a problem of scientific and economic importance. Jensen and Hess prepared a special medium of finely ground spiced ham from a sound can filled into culture tubes half full. This was then wetted down with a .4 per cent solution of sodium nitrate and two per cent of cane sugar. After sterilization the medium was inoculated with Pasteur pipettes from the bottom to the surface. Gas production was indicated by numerous trapped bubbles. Sodium nitrate is essential for gas production.

221. Jensen *et al.* 1934. Ind. Eng. Chem. 26, 1118-1120.

222. Jensen and Hess. 1941. Food Research 6, 75-83; 273-326.

In no case was gas produced when nitrate was absent. It was shown that nitrates, sugars, and cured meat must be present together. When nitrate is absent, anaerobic fermentation may take place.

HAM SOURING, "BONE STINK," OR BONE TAIN

These are terms which have grown up in the industry for a type of spoilage which causes considerable loss. The term "sour" is used to indicate a condition of putrefaction and not formation of acidity, as might be expected. To detect the spoilage an instrument known as a "trier" is used. It is stuck into the ham at various places and withdrawn. If a putrid odor is noted on the trier after it has been withdrawn, the presence of an area of putrefaction within the ham is indicated. Various types of sour hams have been described by McBryde²²³ and Jensen and Hess.²²² The latter prepared a comprehensive discussion of the problem in which results of their own investigations are reported. The six types which Jensen and Hess described are related mainly to the area in the ham which is affected:

- (a) "Shank sour" or sour tibial marrows.
- (b) "Body sour" or sour meat, not marrows. (Also called "loin sour.")
- (c) "Aitchbone sour" or souring of os pubis remaining in the ham.
- (d) "Stifle-joint sour" or souring of area around articulation of femur and tibia-fibula.
- (e) "Body-bone sour" or sour femur marrow.
- (f) "Butt sour" or sours in butt between the aitchbone and muscle.
- (g) "Puffers" or a gaseous condition, no longer encountered.

Microorganisms Involved in Ham Souring. Many different species have been reported as the specific cause. Klein²²⁴ studied so-called miscured hams. From them, he isolated an organism to which the name *Bacillus foedans* was given. His description of "miscured" hams leaves little doubt but that he had what is called today "sour" hams. The organism was anaerobic but spores were not reported. Jensen and Hess²²² equated this organism with *Bacillus putidus* of Weinberg. McBryde,²²³ after a careful study of ham-souring, reported that the anaerobic, sporebearing organism *Clostridium putrefaciens* was the etiologic agent.

Inoculation experiments into soured hams reproduced "bone stink." The organism spread rapidly in hams which were artificially soured. The organism concerned was an anaerobic sporeformer and thus naturally fitted to develop in the interior of the ham. McBryde advised more thorough pumping of the ham with the pickle so that the entire interior would become saturated. The partly pumped or milk-cure hams gave most spoilage.

Clostridium putrefaciens seemed to be sufficiently different from described species to justify a new name. McBryde presented the evidence to show that it differed from Klein's *Bacillus foedans* but did not discuss its relation to *Clostridium putrificum*. A complete description of *Clostridium putrefaciens* may be found in McBryde's bulletin. A few of the salient characters of interest to food bacteriologists will be given. The opti-

imum temperature for growth was 20 to 25°C. (68 to 77°F.). No growth was secured at 37°C. (98.6°F.). At 8 to 10°C. (46.4 to 50°F.) it developed slowly. Furthermore, it was said to develop at 1 to 2°C. (33.8 to 35.6°F.), the temperatures of curing cellars. The vegetative form of the organism was killed in 10 minutes at 55°C. (131°F.). The spores survived a temperature of 80°C. (176°F.) for 20 minutes but were said to have been killed at 100°C. (212°F.) in 10 minutes. McBryde stated that three per cent of sodium chloride or three per cent of potassium nitrate in glucose pork broth inhibited the organism. It was able to live for 30 days in a solution containing 23 per cent of sodium chloride and six per cent of potassium nitrate.

McBryde believed that the organism was introduced into the ham by various instruments, such as thermometers, etc. Boyer and others, as discussed below, reported that it was disseminated throughout the carcass from the moment of slaughter and might be present in the tissues of the living animal. Lewis and Moran¹⁶⁶ attributed sour hams to *Clostridium sporogenes*. They found proteolytic bacteria in fresh hams, a finding in agreement with Boyer. Moran was able to reproduce ham souring in 21 out of 25 inoculations of the specific organism into normal hams. He was able to find no evidence that would relate McBryde's *Clostridium putrefaciens* with his organism isolated from sour hams and believed to be *Clostridium sporogenes*.

It would be logical in such spoilage as sour hams to expect to find *Clostridium putrificum*, as reported by Tucker.¹⁶⁰ Jensen and Hess,²²² however, never encountered it as the cause of sour hams.

Boyer²²⁵ carried out some bacteriological studies on fresh chilled hams as a starting point for a study of the spoilage of sour hams. Twenty-nine hams which had gone through the routine of inspection were examined. The collection period extended over six months. Cultures were taken with the customary precautions. Boyer found that not only the meat but the joint fluid and bone marrow of such hams were hardly ever sterile. Both aerobic and anaerobic bacteria were found. These bacteria are probably the cause of spoilage. Consequently, the development of these forms must be controlled.

Hams from dressed hog carcasses taken from the killing floor 45 minutes after slaughter were found to harbor microorganisms in the interior musculature, synovial fluid, and bone marrow. According to Boyer, the following bacteria were isolated from such hams: *Clostridium putrificum*, *Clostridium histolyticum*, *Clostridium sporogenes*, *Clostridium tertium*, and an unidentified organism resembling *Clostridium oedematiens*. Numerous other organisms also were found.

Jensen and Hess²²² believed that the various types of sour hams are not caused by the same organism which probably helps to explain some of the differences of opinion which obtains as to the etiologic agent. They isolated quite a variety of bacteria which varied according to the type of sour ham examined. They said:

225. Boyer. 1923. Amer. Food J. 18, 197-200; J. Agr. Res. 33 (1926), 761-768.

“The old-style, 60-day cure presented problems in ham souring which were obviated by the quick vein-pump cure of hams. The psychrophiles causing sours in quick-cured hams must grow rapidly at low temperatures.

“The bacteria which can grow at 0 to 3.3°C. (32 to 38°F.) in marrows and the bacteria which are salt tolerant can cause any kind of sour. These bacteria are *Achromobacter*, genus *Bacillus*, *Pseudomonas*, *Proteus* group, *Serratia*, *Clostridia*, micrococci, streptobacilli, and a miscellaneous group.

“Sours in the quick-cured hams are prevented by bleeding hogs properly, adequate refrigeration of carcasses and subsequently the ham, sawing for sealed-shank marrows, prompt handling, bacteriologically controlled pickle, and strict general sanitation in the pork block.”

Origin of Ham-Souring Microorganisms. While some of the earlier investigators made general statements about this subject, we are indebted to Jensen and Hess for a critical discussion. Boyer²²⁵ found no evidence that the organisms found gained entrance through killing floor operations. Boyer concluded that the organisms responsible for ham souring were disseminated through the carcass from the moment of slaughter and are possibly present in the blood and tissues of the living animal. Alteration in killing floor operations was not considered to be of help in preventing development of the causative organism. Prompt handling and adequate chilling were believed to be important. This was confirmed by a low incidence of spoilage where these factors were watched. Jensen and Hess' results indicated that contaminated salt might have a role in ham souring but that curing sugar was without significance. Large nonpermissible amounts of sodium nitrate (exceeding 100 pounds per 1,000 gallons of curing solution permitted by the Bureau of Animal Industry) suppressed bone-souring bacteria. They found that the skin of the neck was heavily seeded with bacteria among which were many anaerobes. These, it was shown, could get into the blood stream when the hog was stuck.

While Jensen and Hess found that normal, prime hogs might harbor bacteria in their blood, organs, and muscle, none of these were of the ham-souring type. They found the blood to be infected by the sticking knife and the sticking operation to introduce ham-souring bacteria into the circulation, bones, and tissues.

Tenderized Hams. These are really precooked hams. The cooking is accomplished by heating, during smoking, at temperatures which destroy connective tissues and make the meat more tender. These hams may also be given a mild cure which has made them popular with the public. Such hams are distinctly perishable products and must be handled as such. Failure to do this has resulted in numerous outbreaks of food poisoning. Slocum and Linden²²⁶ mentioned occurrence of 20 such outbreaks, apparently due to staphylococci, all attributed to ingestion of “ready-to-eat” hams or tongues. They believed that relation of these meats to food poisoning was as great as that of pastry products. Quite a similar situation was reported by the New York State Department of Health²²⁷ where epidemiological evidence again pointed to tenderized hams. One outbreak consisted of five cases in two households. The ham which caused them was steamed

226. Slocum and Linden. 1939. Amer. J. Pub. Health 29, 1326-1330.

227. Health News, N. Y. State Dept. Health 8, (1941), 10-11.

for three hours shortly after purchase and baked for one hour the following day. It was then stored without refrigeration and thus obviously mishandled. The weather at the time was unreasonably warm. Laboratory examination revealed the presence of many *Staphylococcus aureus* and another organism quite like *Escherichia coli*. Moulton²²⁸ classed these hams with custard-filled pastry products. Tendered hams are apparently a good medium for staphylococci.

One outbreak of food poisoning presumably caused by tenderized ham, reported by Bole,²²⁹ may have been due to a member of the genus *Proteus*. Enterotoxin-producing organisms of the genera *Staphylococci* or *Salmonella* were not isolated. Bole suggested that the enterotoxin-producing abilities of *Proteus* species be investigated.

Just where the trouble lies remains to be seen. A good part of it is probably faulty handling after the hams have left the packer. These "ready-to-eat" hams are in quite a different category than the old-type hams which are given a heavier cure and are not precooked. The homemaker may consider tenderized hams to be like the old hams and fail to consider them as perishable products. Tenderized hams must be handled under conditions which will preclude contamination by objectionable microorganisms. The Bureau of Animal Industry in a letter to the New York State Department of Public Health discussed these hams as follows:

"During the last six or eight years there have been three changes taking place in the meat trade: first, a gradual reduction in the salt ingredient in some curing procedures; second, the injection of curing solutions throughout the ham or shoulder either through the circulatory system or by many punctures with hollow needles; and third, the long heating of the cured meat at the time of smoking at relatively low cooking temperatures and for a period of time sufficient to reduce the tenacity of the connective tissues of the meat to render it more tender than meat not so treated would be. In the main, the change in flavor and texture of the meat brought about by the mild cures and "tendering" treatment has gained acceptance in the trade. A good many meat packers are distributing smoked hams that have been in cure a matter of days instead of weeks, as formerly. These new-process hams resemble in outward appearance the old-style hams, but they may be labeled to show that they are ready to eat, as they are, in fact, cooked hams, having been cooked at low temperature, but for many hours so that the heat has reached the inner portions and rendered all portions of the ham acceptable for eating without further cooking, if desired.

"These developments or changes in the meat-curing business, in some cases at least, bring the cured meat into a condition that makes it a favorable medium for the development of organisms if proper care is not taken all along the line from the establishment to the consumer's table.

"In the federally inspected establishments we are taking pains to see that clean practices are followed to avoid in every practicable way the possible contamination of the meat. In most cases of food poisoning which we have looked into, we have found that the trouble comes to the partakers after the meat has been in the keeping of the retailer or the consumer a few days."

BACON

Bacon is a meat specialty prepared by curing, drying, and smoking sides and backs of hogs. Its manufacture is a large industry in America and Canada from which countries large amounts are exported. Methods

228. Moulton. 1940. Natl. Provisioner 103, 13 and 34.

229. Bole. 1940. J. Bact. 39, 343.

for curing bacon are not essentially different from those used in curing of ham. Quality of bacon depends on many factors involving both chemical and bacteriological changes.

Microbiology of Bacon Curing. Microorganisms reduce nitrates in the curing solution to nitrites which in turn impart a red color to the product and probably contribute to the flavor. While these facts are known, not much is known about the species which are involved and the factors which influence their activities. Lochhead²³⁰ tried to count the number of bacteria in a curing solution used in preparation of Wiltshire bacon; he found that usual media and technic were inadequate. A suitable incubation temperature was important as was presence of salt in culture media. The standard procedures with incubation temperature of 37°C.(98.6°F.) showed little more than one per cent of the bacteria revealed when a 10-per cent salt-agar medium was used. Lochhead also found that exposure to tap water for even 45 seconds may kill or inhibit as many as 90 per cent of the countable microorganisms. Contamination of meat to be made into bacon places a larger load on the curing process; furthermore, definitely objectionable species might be introduced which would interfere with the proper changes. Garrard and Lochhead²³¹ isolated 40 microbial types in which Micrococci predominated, which are representative of precuring contamination. Organisms were also found which resembled those in bacon slime. Varying degrees of salt tolerance were noted, micrococci showing the greatest ability to grow at higher concentrations. With 25 per cent of sodium chloride only two species grew. Increasing salt concentrations interfered with nitrate reduction by the bacteria which were able to grow. This suggested that nitrate reduction in curing solutions is a function of the halophilic bacteria rather than of the precuring contaminants. Five groups of microorganisms were made according to their salt resistance or ability to survive. Much greater resistance to salt was shown in curing solutions than in salt broths of similar salt content. Some of the precuring contaminants were able to survive the curing solutions and were suggested as the cause of storage defects. Importance of proper culture media was also shown by results of experiments by Gibbons²³² with representative curing solutions. Highest numbers of bacteria were secured in 10 per cent salt-agar medium incubated at 20°C.(68°F.). The lowest number was secured on nutrient agar incubated at 37°C.(98.6°F.). Counts on media with no salt, four per cent, and 10 per cent of salt incubated at 20°C. gave intermediate values. The number of bacteria in spent curing solutions was higher than in cover solutions. Pumping solutions showed a surprisingly large number of bacteria. Analytical errors owing to sampling, diluting, and counting were relatively small when compared with the other sources of variance. Some of the variations in counts were suggested to be due to presence of different types and species. Gibbons finally concluded that 10 per cent salt agar incubated at 20°C. gave most consistent results.

230. Lochhead. 1938. Prog. Rpts. to Dominion Agr. Bacteriologist for 1934, 1935, 1936. Ottawa, 1938, p. 31.

231. Garrard and Lochhead. 1938. Canad. J. Res. 17, D, 45-58.

232. Gibbons. 1940. Idem 18, 191-201; 202-210; 19 (1941), 61-74.

Results of later investigations by Gibbons and White²³³ indicated little change owing to time or depth in the bacterial content of Wiltshire tank pickle during cure. A decided decrease occurred in the number of bacteria on the surface of the sides. Settling of bacteria from the pickle was not responsible for this increase. Of the normal commercial practices of salting the sides prior to cure and washing and wiping after cure, wiping was the most important in reducing the bacterial population on the surface of the meat. Wiltshire sides, according to Gibbons,²³² are matured for a week or 10 days after removal from the curing tank. During this time microorganisms may develop on them. Whether they are involved in flavor production is not known; however, Gibbons said development may lead to "slime formation" or taint. Visible growth or slime formation became evident when the logarithm of the number of organisms per square centimeter exceeded 7.2. This was not always the case, for some sides did not become slimy at much lower counts while some required many more. This seemed to be related to the species of microorganisms present. The number of bacteria on the sides was found to be correlated with the age of the sides from cure or from packing. The growth rate is slow during the first eight to 10 days from packing, after which it decreases. Sides having an initial load of 100,000 organisms per square centimeter at packing may be expected, according to Gibbons, to remain free from slime for 20 to 25 days if stored at 1.1°C. (34°F.). Gibbons did not observe any correlation between the number of bacteria in the product and the number in the curing solution.

Bone Taint in Bacon. This is a deterioration around the rib bones observed in certain Australian bacon by Smith.²³⁴ The causal agent was found to be an obligate, halophilic bacterium to which the name *Vibrio costicolus* was given. Smith was able to reproduce the defect by inoculation and under controlled conditions of cure. Another halophilic organism, *Vibrio halonitrificans*, was very active in forming nitrite from nitrate. This organism was a strict aerobe and was not believed to possess importance in the regular cure given Australian bacon. Proper conditions for appearance of this bone taint of bacon are favorable temperature and concentration of salt. To prevent development of *Vibrio costicolus* a higher saline level in the curing process at or above the saline death point for the species must be maintained. The organism, it was suggested, might also be controlled by using a dry temperature for the flitch of bacon at or near the death temperature of the organism.

Molds are troublesome microorganisms on smoked meats. Various methods have been proposed for preventing their growth. Many of the procedures have inhibited them but have not entirely prevented development. Francioni²³⁵ found this to be the case with 55 per cent alcohol and dipping in hot water. Rubbing with borax-pepper-molasses mixture also aided in controlling molds. Mold growth was effectively prevented by storing the meat in cottonseed oil. Storing in an atmosphere of carbon

dioxide also restricted mold growth. The value of some of these procedures probably rests on the fact that air supply is cut off. Molds are apparently inhibited by strong currents of air. A forced air stream of five to 12 centimeters per second at temperatures of 3°C.(37.4°F.) to 6°C.(42.8°F.) and with a relative humidity of 90 per cent, according to Kaess,²³⁶ retarded surface growth of *Penicillium flavoglaucum* and *Mucor racemosus*. Retardation was proportional to the velocity of the air current. Carbon dioxide has been found to retard mold development by Moran, Smith, and Tomkins²³⁷; 10 per cent of this gas in air reduced mold growth by one-half. Twenty per cent almost completely inhibited mold development. Similar amounts of nitrogen had no effect.

MEAT PASTES

These products made from various kinds of meat and fish are more popular in England than in America. Their microbiology has been discussed by Crossley.²³⁸ They may be made from any kind of meat or fish which is cooked and then mixed by machinery. Crossley stated that such pastes are then placed in glass jars and sealed with a cover and rubber gasket. These jars are then given a pressure cook for sterilization. Spoilage may be caused by either faulty closure or underprocessing. Bacterial spoilage has been found to be due to *Clostridium sporogenes* and *Clostridium putrificum*. Ten minutes' heating at 115.6°C.(240°F.) was said to be sufficient for destruction of the spores of these organisms as well as the spores of *Clostridium botulinum*. American strains of the latter microorganism are much more resistant. Crossley believed that the final product should be proven by bacteriological methods to be satisfactory before it is shipped. Faulty sterilization was reported by Clarenburg²³⁹ as the cause of spoilage of liver paste.

BACTERIOLOGICAL EXAMINATION OF MEAT

Bacteriological examination is one of several methods used for judging quality of meat. The value of results secured in this manner is still doubtful. Bacteriological methods are valuable, of course, for demonstration of presence of pathogenic bacteria. Whether bacterial standards, such as are used with other foods, can be applied to fresh meat products is still undetermined.

Bickert's²⁴⁰ Method for Bacteriological Examination of Meat and Sausage Products. Appreciating that the usual methods used for bacteriological examination of meat are quite tedious, Bickert undertook investigations to determine their accuracy as well as to search for better methods. He believed that biochemical methods should be used where possible for judging the quality of meat and that bacteriological examination of meat and meat products was feasible only under special circumstances such as research. Routine bacteriological examination of meat is too tedious and there would be considerable uncertainty in interpreting the results.

When bacteriological examinations of meat are to be made, it is essential that the sample be adequate and that it be sufficiently disintegrated. Bickert excluded such

236. Kaess. 1934. Ztschr. f. Gestützk. Kälteindus. Beih. 31, 153-156; 96-102.

237. Moran, Smith, and Tomkins. 1932. Soc. Chem. Indus. J. 51, 114-116T.

238. Crossley. 1938. J. Hyg. 38, 205-216.

239. Clarenburg. 1931. Tijdschr. u. Diergencesk. 58, 1331-1333.

240. Bickert. 1930. Ztschr. f. Untersuch. der Lebensmtl. 59, 345-364.

implements as mortars for disintegrating the meat on account of the possibility of contamination. He suggested the use of a ball mill with quartz sand and a little physiological sodium chloride solution to give fluidity. Twenty grams of meat were ground with 20 grams of sterile quartz sand and 80 ml. of sterile physiological salt solution for one hour at 120 rotations per minute. This is then brought to 200 ml. with sterile salt solution and carefully mixed for 15 minutes. This material is then sampled for enumeration of microorganisms. Gelatin and agar were used as the plating medium. Bickert rightly placed very little confidence in results secured by plating. He compared a number of available methods for enumerating bacteria and reached the conclusion that a new one was needed. The method which was finally developed seems to be a modification of that proposed by Fries.²⁴¹ Bickert, however, substituted for the yeast cells, spores of saprophytic bacteria or Staphylococci since there was then less difference in size. The spores were treated with cold silver-nitrate solution and a reducing agent in order to make them more suitable for the method. A cold saturated solution of silver nitrate was carefully flowed onto an agar slant culture of the spore forms to be used. After three to five minutes it was removed and the slant washed several times with distilled water in order to remove all of the silver nitrate. This was followed by a reducing agent (two to four grams of pyrogallie acid and five ml. of formalin in 100 ml. of water). The reducing agent causes the silver nitrate treated spores to assume a black color. Excess of reducing fluid should be removed by repeated washing.

The bacterial content of the material to be tested is determined by mixing it (nine parts) with the standard fluid (one part). A drop of carbol fuchsin is then added. The spores remain black while the bacteria are stained red. A drop of this well-mixed fluid is transferred to a slide by means of a pipette and a cover glass dropped over it. This is carefully pressed down and sealed with vaseline or wax. The slide is counted, the calculation being made as follows:

$$X = \frac{\text{Vol. of Test Fluid}}{\text{Vol. of Bacterial Fluid}} \times \frac{\text{Sum of Counted Bacteria}}{\text{Sum of Counted Test Bacteria}} \times K$$

X = Count of unknown.
K = Count of the test fluid or suspension.

The standard suspension should be diluted if necessary. The mixture should be such that there are from five to eight bacteria in each field.

The standard suspension should be counted by a hemacytometer counting chamber. **Hoagland, McBryde, and Powick's²⁴² Method of Meat Examination.** The following technic was used by these investigators in a study of the changes in fresh beef during storage. The method will be given as the authors reported it.

In examining the quarters bacteriologically the following procedure was adopted: A slice or section from three to four inches thick was cut from the upper portion of the round. From this slice a rectangular block extending from the outer surface to the bone was cut. (An illustration is given in the original paper.) This block, which measured about four and one-half to eight inches and weighed from six to eight pounds, was first immersed in actively boiling water for three minutes, next in bichloride solution (.5 per cent) for five minutes, and was then wrapped in sterile gauze which had been wrung out in the bichloride solution. This was done in order to sterilize the surface of the meat and to prevent the growth and possible penetration of bacteria from the outside, pending the taking of cultures. It was not always possible to make cultures immediately, but they were always made within two hours; and during this time the block of meat was kept wrapped in the bichloride gauze and at cold-storage temperature 1.1 to 2.2°C. (34 to 36°F.).

The short immersion in the boiling water served to coagulate the muscle protein to the depth of three to five mm., but did not cause sufficient elevation of the inside temperature to have any injurious effect on the bacteria present. A test was made by

241. Fries. 1921. *Centbl. f. Bakt.* 86, 90-96.

242. Hoagland, McBryde, and Powick. 1917. U. S. Dept. Agr., Bur. Anim. Indus. Bull. 433, Feb. 15, 1917.

introducing a thermometer into a block of meat of the size described above so that the bulb rested at the center of the great mass, and there was no appreciable rise in temperature during the three-minute interval in the hot water. The outer zone of coagulated protein served to prevent the penetration of the bichloride solution into the meat.

Beginning about one inch from the outer surface a series of cultures were taken at intervals of an inch, proceeding from the outside toward the bone, and these cultures were numbered as indicated in a diagram. In taking the cultures a series of sterile scalpels were used, one being used to cut through the outer or surface portion, and others to make deeper cuts in order not to carry in any of the bichloride solution adhering to the surface of the meat. Plugs of meat about a centimeter square were used in making the cultures. Cultures were made in neutral beef broth and in glucose agar from which the air had been expelled by boiling. When clouding occurred in the bouillon cultures, agar plates were poured and the organisms present were plated out.

Garrard and Lochhead's²³¹ Method for Determining Bacteria on Surface of Meat. These authors used what they termed a filter paper impression method using Whatman No. 3 filter paper cut into squares of four sq. cm. and sterilized in Petri dishes in hot air at 120°C.(248°F.). Samples were taken by pressing a square of filter paper firmly against the meat tissue for 20 seconds with sterile forceps; the square was then dropped into a 750-ml. Erlenmeyer flask containing 500 ml. of physiological salt solution and 75 grams of broken glass. The flasks were shaken until the filter paper was disintegrated. The contents of the flask were then plated with nutrient agar in the usual manner. Garrard and Lochhead combined the contents of flasks in order to pool the samples when they desired to do so. The observations of Wilson²⁴³ are pertinent.

Bacteriological examination of cured meats and curing solutions require special media, as shown by Garrard and Lochhead,²³¹ Landerkin,²⁴⁴ and Cook, Gibbons, Wingler, and White.²⁴⁵ In general these investigators reported that the rate of colony development and the total number of colonies varied with the salt concentration of the medium. Landerkin also found that incubation of plates at 20°C.(68°F.) resulted in higher counts than at 37°C.(98.6°F.). Bacterial counts on 5-, 10-, and 15-per cent salt agars showed a definite relation to each other on over 200 samples taken over five years. Such results indicate the importance of using the right media.

Crossley's²²⁸ Method for Examination of Meat and Meat Products. Crossley proposed a new method for examination of meat and meat products using milk as a basic medium in place of meat and egg preparations. He summarized the method as follows:

Medium: Skimmed milk containing one per cent of peptone and .01 per cent of brom-cresol-purple is tubed in 10-ml. quantities and heated in the Arnold steam sterilizer for 20 minutes on four successive days. Control tubes should be incubated. The peptone is not essential but shortens the reaction time.

Inoculation: One and one-half to two grams of paste taken from the center of a jar with a sterile instrument (spatula or section lifter) are inoculated into a tube of medium. This heavy inoculation of paste is an essential part of the procedure.

Incubation: The tubes are incubated from three to four days at 37°C.(98.6°F.). The tubes do not need to be made anaerobic either with paraffin or reduced iron.

Types of Reaction: These are essentially those secured with the Ayer's milk tube described in the chapter on milk.

CANNED MEATS AND MEAT PRODUCTS

Canned meats and meat products are now a regular part of the diet of man. While considered in former times to be the cause of much illness,

243. Wilson. 1922. J. Bact. 7, 405-446.

244. Landerkin. 1940. Food Research 5, 205-222.

245. Cook *et al.* 1940. Canad. J. Res., Sect. D, 18, 123-134.

public confidence has been regained. Many of the early statements about the danger of canned meats were based on assumptions with little or no satisfactory evidence to support them. Canned meats are satisfactory products today, and add variety to the diet. In early times, sailors and others who were away from supplies of fresh meat had to use salt meat entirely. Appert's²⁴⁶ statement regarding the benefits of his method of preservation were certainly not overstressed. Emergency food rations made up largely of meat and meat products are of great importance in wars and explorations.

Procedures Used in Canning Meats. The general procedures of canning meats are not unlike those discussed in Chapter 23 for vegetables.

Containers. These may be either of glass or tin. The tin containers are probably most commonly used on account of the ease with which they can be handled. They may be processed with greater ease, also. The tin can has been discussed fully in Chapter 23.

With some meat products zinc compounds, such as zinc oxide, may be incorporated in the enamel to prevent sulfide discoloration. Enamel containing the zinc ion, according to Hallman,²⁴⁷ is known as "C" enamel.

Precooking. Practically all meat is cooked to a greater or lesser extent before being placed in the can. This treatment tends to reduce the bulk.

Canning. This is done either by hand or machinery. Meats packed in glass containers are usually packed by hand. Such meat products as potted meat, hash, etc., may be placed in the cans by an automatic filling machine. After the cans are filled, they are sealed on the closing machine.

Exhausting. Vacuum is just as desirable in canned meats as in vegetables. It has been discussed in Chapter 23. It has the same function in canned meats that it has in canned vegetables, i.e., to relieve the stress on the closed container during processing, to prevent discoloration of the product, provide concave ends by which the consumer may determine that the product has not spoiled, to prevent "flippers" at high altitudes, etc. Vacuum-packed foods are known to be superior to those which are not.

Weiner²⁴⁸ reviewed the various methods for securing vacuum in meat cans. While the vacuum-closing machine may be the best way of securing vacuum in some products, it is not so satisfactory for others.

Processing. As soon after filling as possible, the cans should be processed. A long delay between filling and processing allows development of bacteria which in turn places a heavier load on the process. A discussion of processing as applied to various foods, has been given in Chapter 23. Many of the principles discussed there are applicable to meats. However, it is probably true that much less is known about the facts involved in processing meats than is known with respect to many other foods. The time and temperature of the process is determined by factors, such as the size of the can, the character of the product—whether it is solidly packed with no free liquor or whether there is free liquor to aid in carrying the heat into the can—and a number of other factors. Kossowicz²⁴⁹ recommended that meat packed in 250-ml. tins should receive a cook of at least 120 to 125°C. (248 to 257°F.) for 45 minutes. With this process, he secured very little spoilage. Muntch²⁵⁰ believed that in processing canned meats the center of the can must reach 120°C.

Sterilization of canned meat products is a more difficult problem than sterilization of certain canned vegetables and fruits. Canned meat products are more compact and have much less water. The center of the can must reach retort temperature in order to secure a product which will keep. Clarenburg and Zwart²⁵¹ claimed that the bacterial

246. Appert, N. See Chapter 23 for reference.

247. Hallman. 1936. *Canning Age* 17, 196-199.

248. Weiner. 1936.

249. Kossowicz. 1917. *Chem. Ztg.* 41, 673-674.

250. Muntch. 1931. *Ztschr. f. Hyg. u. Infektionskrank.* 112, 395-412.

251. Clarenburg and Zwart. 1937. *Tijdschr. u. Diergeneesk.* 64, 383-397

load in the meat product was the factor which really determined the process which had to be used. A culture of *Clostridium botulinum* containing 35,000 spores required 50 minutes' heating at 115°C.(239°F.) to destroy it, while only 10 minutes were required when 13 spores were present. Data on the time factor indicated that the strain used by Clarenburg and Zwart was less resistant than most American strains. Attempts to learn more about heat resistance of bacterial spores in canned meats led Gutschmidt²⁵² to heat spores treated in different ways. He found that spores coated with a layer of coagulated serum or fat were much more resistant to heat than untreated spores. The former required 20 minutes at 120°C.(248°F.) for destruction, while the latter required only six minutes. Five minutes at 134°C.(273.2°F.) was the optimum time required to kill unprotected spores. With the cans which Gutschmidt used 60 minutes were required for the center of the can to reach this temperature. This higher temperature of sterilization resulted in a better product than a lower temperature.

A distinction is made between "absolute" and "commercial" sterility of canned meats as is done with other canned foods. Commercial sterility is that condition in which viable bacteria are present but they do not develop to cause spoilage.

Heat Penetration Into Canned Meats. In general canned meats permit somewhat slower penetration of heat than many other foods. They are solidly packed and heat must enter by conduction and not by convection.

Cooling of Canned Meats. This process is just as necessary with canned meats as it is with other foods. The quality of the product may be harmed if cooling is not promptly and adequately done. Hallman²⁵³ said that the temperature of the can after cooling should not exceed 40.6°C.(105°F.). This is in order to prevent spoilage by thermophilic bacteria which grow in a temperature range of 43.3 and 71.1°C.(110 and 160°F.). Cooling may be accomplished in different ways. The cans may be cooled in the retort with cold water or placed in it after removal from the retort. They may also be cooled in the retort under pressure. Hallman stated that spray cooling was becoming quite popular among meat canners.

BACTERIA IN CANNED MEATS

Viable bacteria were once believed to be present in most cans of meat or meat products. While this may have been the case in the early days of the canning industry, it is probably no longer true. The advances in plant sanitation and processing have yielded a product which is quite free from viable bacteria. Results reported in the earlier literature probably no longer hold for the modern product. In some cases these results were based on contaminated plates, for it is not easy to open cans without introducing foreign bacteria.

Those bacteria which have been reported, in general, have been anaerobic sporeformers. *Clostridium welchii* was observed to be the cause of swells in canned beef by McClung and Wheaton.²⁵⁴ It was present in the raw beef and was not destroyed during parboiling at a temperature of approximately 100 to 110°C.(212 to 230°F.). Delays in the canning procedure allowed gas to be formed; this caused swelling of the cans. The organism was killed during processing so no health hazard was involved.

Thermophilic Bacteria in Canned Meats. These bacteria which have been so important in canned vegetables have not been important in canned

252. Gutschmidt. 1934. Veröffentl. aus dem Gebiete des Heeres Sanitätswesen. 90, 61-80.

253. Hallman. 1938. The Canner, Conv. Number.

254. McClung and Wheaton. 1936. Food Research 1, 307-318.

meats, at least those to which no cereals are added. Recently, Jensen and Hess²⁵⁵ pointed out that thermophilic sporeforming bacteria have become significant in meat products to which soya flour, grits, or meal have been added. However, if specific conditions of treatment are observed, these bacteria are restrained in their action as long as 50 days, according to results of one experiment. Thermophilic spoilage was said to be inhibited by curing with three and one-half pounds of sodium chloride, two and one-third ounces of sodium nitrate, and one-eighth ounce of sodium nitrite per 100 pounds of meat if the six-pound can and contents are retorted at 112.7°C. (235°F.) for three hours, 20 minutes after evacuating and sealing.

BACTERIAL EXAMINATION OF CANNED MEATS

The gross technic does not differ much from that used with other canned foods. Special attention is usually given to the media used. Canned meats are submitted to the laboratory for one of the following reasons (Cameron²⁵⁶):

1. Unspoiled samples—for examination for sterility.
2. Unspoiled samples—for examination for keeping quality.
3. Spoiled samples—for examination for causes of spoilage.

Frei and Krupski,²⁵⁷ who discussed this subject, stated that leaking cans will usually show a flora made up of bacteria, yeasts, and molds. He observed that cans with flat or concave ends might contain viable bacteria. Seeberger²⁵⁸ relied much on the sound of cans when shaken. This, at best, would be a questionable method for cans which were just beginning to spoil. Where the contents had undergone marked spoilage, this test might be of some value.

Considerable study was given this subject by Savage,²⁵⁹ in England. Observations were first made on canned foods at five ports of entry. Savage stated that considerable trouble was experienced with leaking cans.

Savage²⁶⁰ studied the methods for the examination of canned meats at various places in England and outlined the following procedure for the ports of entry in England:

A. *Extent to which the tins are examined.* The actual number of tins in any one consignment is usually so large, often running into tens of thousands, that it is impracticable, and experience shows it to be unnecessary, to examine each tin separately and a working compromise is adopted which varies slightly in the different ports studied.

In all the ports there is an examination by the trade for their own purposes which primarily has nothing to do with the question of suitability or unsuitability for food. It is obviously of importance for commercial purposes for the trade to know the proportion of rejects. The plan generally adopted is for the canned meat to be examined at the wharf by the wharfingers, and usually 10 per cent of these cans are examined. The allowance for rejects is based upon this 10-per cent examination.

This trade examination is utilized by the Food Inspectors who are always about these wharfs. If only a small portion of this 10 per cent is rejected by the trade then

255. Jensen and Hess. 1943. Food Indus. 15, 66-67.

256. Cameron. 1937. Assoc. Off. Agr. Chem. J., Aug. 1937, 429-432; also Aug. 1936, 433-438.

257. Frei and Krupski. 1919. Schweiz. Arch. f. Tierheilk 60, 445-470.

258. Seeberger. 1919. Schweiz. Arch. f. Tierheilk 61, 367-377.

259. Savage. 1920. (Gt. Brit.) Food Invest. Bd., Spec. Rpt. No. 3.

260. Savage. 1922. (Gt. Brit.) Food Invest. Bd., Spec. Rpt. No. 10.

this is generally accepted and the whole consignment is passed. If the percentage rejected is considerable, the consignment is stopped pending an examination of the whole parcel. This again is usually done by the wharfinger's men, constantly controlled by the Food Inspector.

The same percentage is not adopted throughout, nor it is clear that any very hard and fast figure is used. At Bermondsey (London) the Port Authority's inspectors go through the whole consignment if more than two and one-half per cent of the 10 per cent examined is rejected. In Stepney (London), Bristol, and Manchester no definite figure is adopted, but in practice it is about this amount. At Liverpool, if less than two per cent is rejected, the consignment is passed.

Some such procedure is the only one practicable under the circumstances and seems to work well in practice. The wharfinger men are impartial, and there is no inducement for them to be otherwise. From the trade point of view it is important not to pass any consignment with a high proportion of rejects, since the larger retailers to whom the cases are sent are well acquainted with the signs of defective tins and will certainly throw them out, erring, if anything, on the side of an undue stringency, since the local retailer will not accept any tin with the slightest sign of defect.

Indeed, while on the one hand there is but little likelihood of the trade examiners passing unsound tins, there is a decided tendency for them to reject tins which may be perfectly good, but which, not coming up to the standard of the ultimate retailer, would be rejected by him and charged back upon the wholesale importer. This point is of great importance to the importer and large retailer and will be referred to again below.

It is evident that the value of the procedure set out above must turn essentially upon the capability of the wharfinger examiners, but this point is more conveniently discussed after the actual methods employed have been considered.

B. The criteria relied upon to detect unfit cans. With some modifications as to interpretation, the methods employed in the different ports are throughout the same. A full examination of the unopened tin comprises inspection, palpation, percussion, and sometimes shaking, a form of auscultation. To a doctor, therefore, the methods employed strikingly resemble those employed by him for the physical examination of the human chest.

Inspection. Well-defined holes, marked indentations, and other signs of gross ill-usage are at once detected by inspection.

Signs of extensive rust may not indicate anything against the contents, but they lessen the commercial value of the parcel and, when extensive, have on this ground to be dealt with by the trade. Also, if there is much rust, it is extremely likely that a proportion of the tins will have rusted through in places and so give rise to a high proportion of leaky tins, which will have increased by the time the tins reach the consumer.

Consignments with many rusty tins are therefore subjected to special scrutiny and are frequently all looked over and treated by repainting. A parcel treated at Liverpool warehouse may be given as an illustration. In this case the cause of the rust was the common one of the labels being put on and pasted all over the tin with paste too wet. The excess water caused rusting, indicated by the labels being marked extensively with a number of brown stains. With many of the tins, the process had gone so far as to cause definite perforations. The whole consignment was treated by having the labels scraped off and the rust marks examined. If the tins were sound they were repainted and relabelled, the fresh labels being wrapped round and pasted only along a narrow strip instead of all over.

The most important defect detected by inspection is the presence of any swelling or "blowing." In general, this is accepted as a sign of gaseous decomposition of the meat, and is shown by the ordinary flat or slightly concave surface being bulged, owing to the presence of the gases of decomposition within. Although easy of detection and deduction, common sense has to be employed if mistakes are to be avoided.

As explained above, the presence of a vacuum insures the meat being in contact with the tin all over. If, therefore, the tin is subjected to ill-usage and dents are caused,

it is obvious that this will cause the tin to bulge slightly elsewhere to find room for the meat. The presence of a bulge in such specimens should not give rise to difficulty as the cause is so manifest.

Theoretically, some light bulge might be due to overfilling with meat, but this does not often occur with tins as imported, as overfilled cans are detected at the cannery and returned to be better filled.

Definite bulging of the tin, if meat is the food packed, is, in general, reliable evidence of the presence of gas within the tin, and such gases with this kind of food are invariably due to bacteria, and therefore justify rejection.

Inspection will also show the number of vent holes, but this is not of much practical assistance. It is sometimes assumed that the presence of a second vent hole indicates that the tins have been vented to let out gases caused by bacterial decomposition, and then resealed. In reality, such procedure would be of no practical use in the case of meat products. Meat infected with bacteria sufficient to produce gases in amount to cause definite blowing would almost certainly be of bad odor. Apart from any question of commercial honesty, it would not pay commercially to try to sell such meat, as the loss of reputation would be too serious. It is not merely a question of venting and resealing; the meat in the tin would have to be heated to a high temperature both to kill contained bacteria and to ensure a vacuum when it cooled. On the other hand, during the canning of meat several contingencies may occur which makes it a perfectly legitimate procedure to make a second solder hole, and this without casting the slightest aspersion upon the character of the meat.

In one factory in Chicago, tinned mutton was being put up in cans, the central hole of the tops being closed when cold, i.e., without any vacuum. The cans were then heated in the kettles and vented when taken out by the central hole being touched with a hot iron to melt the solder. They were resealed immediately after the escape of the air and steam. In this way a good vacuum was obtained. The venting might equally well have been done through a fresh hole, and then there would have been two vent holes without any reflection upon the quality of the meat.

No adverse significance can be attached to the presence of more than one solder hole in otherwise sound tins of meat.

Palpation. The Inspector picks up the can to examine it, and so in this way at once notices any change from the normal feel. When the vacuum is lost the tin ceases to be closely adherent to the meat, in one or more places or even extensively, and there is a springy feel which is quite distinctive. This loss of vacuum can only be due to access of air or production of gas, and is therefore always associated with a definite note when percussed.

Percussion. In practice apart from obviously blown or otherwise obtrusively unsound tins, reliance is placed mainly upon percussion, i.e., the character of the sound yielded by tapping the surface of the tin. This is usually done by a piece of wood, but some inspectors prefer their fingers.

As already explained, the cans are so sealed as to ensure that there is considerable vacuum inside when they cool. The pressure of the outside atmosphere insures that the meat is in contact with the tin all over. In consequence, when such a sound tin is struck anywhere (except often immediately under the cap) it emits a dull note. If not in contact there is air or other form of gas and the note is tympanitic.

In practice, it is commonest to find the note defective in parts only and not all over, but in bad cases it may be defective over every part of the tin.

The procedure generally followed is to reject tins which fail to give the normal dull note everywhere, but some differences in practice were met.

In certain of the areas investigated all such tins were thrown out, but in other districts rather more latitude was allowed. Thus, in both Liverpool and Manchester it was recognized that a defective note at either end only might be due to insufficient filling, and the tins would be passed. At Manchester, they employ the common sense practice of opening one or two such tins of any consignment actually to see their condition, and then if these are found good the whole consignment is passed.

Shaking. Only if the meat is in an advanced stage of decomposition and partially liquid are any results of value likely to be obtained. The ordinary canned meat tin is solid throughout and yields no sound on shaking.

When fresh meat, i.e., not salted or corned, is canned, a little water is usually added to prevent the final product being too dry, and it is possible through careless manipulation for this to be excessive. Such tins, when shaken, shake loose with a characteristic sound, and although they may be perfectly good are liable to be rejected by the retail trade.

The following is an example of such a consignment. A parcel of several thousand one-pound tins of a well-known brand came to the port of Bristol and were passed as sound by the Food Inspector at Avonmouth. They then came into Bristol by road, and the purchasers had the usual 10-per cent examination made. A considerable proportion of the tins were found to be what the trade call "sloppy," i.e., the contents shook about and evidently liquid was present. The purchasers in consequence refused to accept the consignment unless the Health Department would certify the tins as good, although they had already been passed. The percentage of blown tins was small and not above the average. Six of the "sloppy" tins were examined in the laboratory and all were found sterile and the meat in good condition, apart from a little excess of liquid of no importance from the standpoint of health.

A very large number of tins have to be examined, and while the above methods are all employed if necessary, in practice the examination is very rapid. The Inspector has each case emptied out on a table. He then picks up each tin in turn. A very superficial scrutiny is sufficient while almost subconsciously the feel of it in his fingers will detect any springy areas. He then taps each tin in a number of places. If satisfied as to the sound note and the impression conveyed through his fingers the Inspector passes the tin, while those not satisfactory in any particular are subjected to a more careful examination along the same lines.

In this way, many hundreds of tins can be easily examined within an hour without much risk of anything abnormal being overlooked.

In order to prove the merit of the above procedure Savage visited the wharves and received the tins for laboratory studies after they had been passed by the inspectors. He found that many satisfactory tins of meat were being rejected with an unnecessary consequent economic loss. This made it apparent that some improvements should be made in several directions.

1. Utilization of the above tests but with different standards on the part of inspectors.
2. Preparation of additional physical tests.
3. Opening the cans for examination.

National Canners Association²⁴⁶ Suggested Procedures for Examination of Canned Meat Products. The Technical Meat Committee of this association has found the following procedures to be satisfactory. In these procedures more attention is given to the media to be used to favor development of spoilage bacteria.

(a) Before being cultured, unspoiled samples submitted for examination as to keeping quality should be incubated at 37.5°C. for a period of one month. This time of incubation, necessarily an arbitrary matter, is considered the longest period that is practicable in the usual case. Anaerobes, which at times may remain dormant for many months, may escape detection, but usually the likelihood of spoilage in the product under ordinary commercial conditions of handling is indicated in this time. It is regarded as unnecessary to incubate at thermophilic temperature, i.e., 55°C., because such spoilage in meat products is extremely rare.

(b) Samples submitted for examination for cause of spoilage should be given direct microscopical examination in order to obtain general information regarding the bacterial flora. Ordinary laboratory stains, such as carbol fuchsin or gentian violet, are suitable in preparing mounts. The gram stain is not recommended. A gram-negative result

would be of little significance because of lack of knowledge regarding the age of the bacteria in the spoiled material.

The various steps in culturing technique are described in order as follows:

A. Physical examination and preparation of the can:

1. Note and record all marks of identification, either embossed on the can or appearing on the label.

2. Remove labels. Record any physical defects, such as rustiness, pinholing, dents, improper closure, or defective side seams. Plainly mark for inspection questionable points if the can is to be pumped or given any other physical examination after it is opened.

3. Clean the container with soap and water; if it is greasy, it may be found helpful, especially at the site of opening, to apply a suitable solvent, such as petroleum ether, alcohol, or naphtha.

4. For sterilization at the site of opening, preferably grasp the container in the hand and hold the previously cleaned top in the flame of a Bunsen burner, distributing the heat with a circular motion. Do not play the burner down upon the top of the can because this will result in a concentration of heat at the top, causing scorching of the material, and it might lead to spurting of the contents when the opening is made. Such sterilization also causes a release of vacuum in the can, which will prevent any contamination that might result from an inrush of air when the opening is made. When containers are badly swollen, it may be unwise to flame in the manner described. In such instances apply the treatment described by Fellers,²⁶¹ who suggests sterilization with bichloride of mercury (1 + 1000). As an alternative it is suggested that the cans be thoroughly cleaned with 60 per cent alcohol. Whichever later treatment is used, first thoroughly cleanse the cans with soap and water, as it is possible that neither the bichloride nor the alcohol treatment would insure complete destruction of spore contaminants in the time that elapses between the sterilization treatment and the opening of the container. Thus mechanical removal of contamination should be regarded as an essential partial treatment.

B. Removal of sample:

1. *Opening of container.* After flaming, or otherwise sterilizing the point of opening, make an aperture with an appropriate type of opener, which has also previously been sterilized by flaming. (Openers of the spiral or circular type, which cut a circular disk around a central puncture made by the instrument, are preferred, because those that make the cut at the can seam offer greater opportunity for the contamination that arises from excessive manipulation and greater surface exposure.) With liquid products, puncture an opening with a sharpened instrument of appropriate diameter. This subject has been discussed in detail by Tanner.²⁶²

2. *Inoculum.* As suggested by Tanner (*ibid.*), determine the type of instrument used for the removal of the inoculum by the character of the food under examination. Sample liquid or semiliquid food products with sterile untapered pipets or inverted 10-ml. pipets. Sample solid material with sterile cork borers or brass sampling tubes after they have been wrapped in paper and sterilized for 30 minutes at 15 pounds in the autoclave. Stopper the samples with cotton plugs, and force the solid material into culture tubes by means of a sterile glass rod or some similar device. As also suggested by Tanner, the sample should consist of at least 15 grams of food material, which may be cultured directly into one culture tube or flask, but preferably into at least three culture vessels. If the material is solid, mix it with sterile water as a preliminary step to inoculation.

3. *Sampling of product fractions.* If it seems to be desirable to obtain inocula from component parts (fat-liquid-meat) of unspoiled canned meats, use special procedures based upon pre-incubation at a relatively high temperature. This has been done with

261. Fellers. 1936. *Assoc. Off. Agr. Chem. J.* 19, 430.

262. Tanner. 1936. *Idem* 19, 432.

roast beef in 24-ounce cans, corned beef in six-pound soldered cans, and Vienna sausage in one-half-pound cans.

Descriptive procedures are as follows:

Roast beef:

Separate roast beef into its component parts by pre-incubation at 50°C. for 24 hours. Draw off the liquid portion into a sterile, glass-stoppered, wide-mouthed bottle, and place in the incubator to permit the fat to separate from the liquid portion. Pipet off 10 ml. of the separated fat layer and add to 25-30 ml. of a dispersing agent (two per cent gum tragacanth and one per cent gum arabic in water). Agitate the fat and dispersing agent well in a mechanical agitator and make inoculations. Pipet samples of the liquid portion from underneath the fat layer and culture directly. After freeing the meat from all liquid, remove with a sterile cork borer and culture.

Corned beef:

Separate the fat by incubating at 50°C. for two days and then chilling immediately. (This results in the separation of a large amount of fat.) After chilling, open the cans at two points: (a) at the top, at which point a fat sample can be obtained, and (b) on the side or about the center, removing the sample of meat by a sterile cork borer. Add the fat to the dispersing agent and culture, but culture the meat directly.

Vienna sausage:

Prior to opening, incubate the cans 24 hours at 37°C. Remove liquid samples by means of sterile pipets inserted through an opening in the top of the can. After removing all liquid, mash the sausages in the same can and remove samples for culture.

In a meat product that is processed under pressure, understerilization usually results in the survival of sporeforming anaerobes—principally those of the putrefactive group. Thus anaerobic media are of special importance in the examination of canned meats. In addition, as a preliminary to plating and pure culture study, enrichment media are necessary to propagate nonsporing bacteria and aerobic or facultative anaerobic sporeformers. The following media are recommended for the purposes indicated. Special media for thermophilic bacteria are not necessary.

(1) *Veal infusion broth*. This medium is satisfactory both as an enrichment medium and as a propagator of anaerobes. It is prepared as a standardized, dehydrated product and is marketed under the name of "Bacto-veal Infusion Medium" by the Difco Laboratories, Inc., Detroit, Michigan. Because of its standardization, its use in this form is recommended.

(2) *Bacto-nutrient broth*. Recommended as an alternative enrichment medium. This product is also manufactured in dehydrated form by the Difco Laboratories, Inc.

(3) *Liver broth and beef heart peptic digest*. Recommended as an alternative anaerobic media. These products were described in a previous report.²⁶³

As to culture methods for further study of the organisms isolated by enrichment, it is recommended that The Manual of Methods for Pure Culture Study of Bacteria of the Society of American Bacteriologists serve as a guide.

D. Routine examination:

It is recommended that original cultures be incubated at 37.5°C. for 48-72 hours.

Jellied Meat Products. These products are subject to spoilage by bacteria from various sources. Allen²⁶⁴ found the empty cans to be heavily laden with bacteria and molds, many of which were removed by steaming. The gelatin used for filling the space between the meat also carried many bacteria. When these products spoiled, it started on the surface. Aerobic and anaerobic cultures showed the presence of *Bacillus subtilis*, *Bacillus proteus*, and *Bacillus mesentericus*. *Clostridium welchii* was

263. Cameron. 1936. Idem 19, 436.

264. Allen. 1919. Amer. Vet. Med. Assoc. J. 14, 394-397.

found in several specimens. No members of the *Salmonella* group were found.

Allen reported the results of several attempts to sterilize gelatin and jellied meat products. It was the general feeling among packers that sterilization in the final package at a temperature sufficiently high to destroy the bacteria, might harm the jellying powers of the gelatin. Allen found, however, that a jelly of good consistency could be held in an autoclave at a temperature of 115.6°C.(240°F.) for as long as 35 minutes without affecting the product. A poor jelly, however, could not be so treated. Several experimental packs were put up, the results of which showed that sterilization in the final package under pressure was possible.

Mincemeat. This is a meat product which has much favor in America. It is a heavily spiced mixture of chopped meat, apples, and raisins. The preservation of mincemeat is probably due to its content of spices and acids. Bachmann²⁶⁷ has shown from experiments carried out in the laboratory that *Clostridium botulinum* would grow in mincemeat with indications of spoilage after a week. Bachmann stated that mincemeat should be completely sterilized or else heated to the boiling point before tasting. Sterilization of mincemeat in tin or glass containers is not difficult because heat does not cause deterioration. It is processed in the hot-water bath with success.

Meat products have caused a little botulism. While Bidault²⁶⁵ and Curfman²⁶⁶ have shown this possibility, meats have been remarkably free when the vast amount which has been used is considered.

Home-Canned Meats. The basic principles are the same as those discussed elsewhere for factory-canned meats. Both glass jars and tin cans are used by the home canner. Nelson and Berrigan²⁶⁸ and Nelson and Knowles²⁶⁸ studied rates of heat penetration into meats packed in tin cans and in glass jars. They used a 12-quart pressure cooker the cover of which was provided with a thermometer which extended into the center of the can. This technic was not the best for it has been found that thermocouples avoid some of the errors introduced by thermometers. They also inoculated the meat with test organisms: *Clostridium botulinum*, *Escherichia coli*, a heat-resistant strain of *Streptococcus fecalis*, and *Bacillus mesentericus*. In solid meat packs 10 pounds of steam, 115.5°C.(240°F.), were insufficient to destroy the bacteria used as test organisms. Sterilization of No. 2 cans was obtained with 15 pounds pressure at 121°C. (249.8°F) for 65 minutes.

Home-canned meats should be processed only under steam pressure at temperatures and times which have been found to be adequate. Boiling water processes are inadequate to prevent spoilage and may be dangerous.

Serological Identification of Meats. These procedures are used to detect substitution of one type of meat for another, usually, though not always, a cheaper meat for a more expensive. The best-known serological method

for this purpose is the precipitin test. It is based on the fact that *precipitins* appear in the blood serum of animals which receive intraperitoneal injections of a foreign protein, such as blood serum of another animal or an extract of the tissues of another animal. When the blood serum of this first animal is mixed with the antigen (extract of tissue, blood serum, etc.) a cloudy precipitate forms. The precipitate appears only when the prepared rabbit-blood serum is mixed with the substance with which the rabbit was injected. In this manner, it is possible to inject a number of rabbits with various substances which it may be desired to test for and have them on hand ready for use. The technic is a precise one and must be carefully carried out.

This method has not been widely used in America for there is not the need for it as in some foreign countries where flesh of certain animals, such as the horse, is used for food. Countries in which large amounts of sausage are eaten have used the precipitin test for detecting presence of certain proteins. It is desirable in some cases to know whether ingredients contain pork or horseflesh. Roza and Mazzaracchio²⁶⁹ and Piegai²⁷⁰ used the precipitin test for these purposes. They found the test to be useful in sausage analysis if due precautions were taken for avoiding error and for proteins which had not been completely coagulated or denatured by heat. For sausages which had been cooked so long that the protein had been completely denatured, some success was achieved by pancreatic digestion before making the test. Piegai found that he could detect the presence of mutton in beef sausage or vice versa even in amounts of five per cent or less. It had been believed generally that the precipitin test could not be used with closely related zoological species. He was also able to use the test in identifying pork and horseflesh in sausage when the state of putrefaction might cause a negative result to be expected.

Identification of Meat With Precipitin Test. The precipitin test seems to have been of greatest use, for detecting horse meat in sausage or proving that deer had been slain out of season. The test may be applied to salted and to cooked meats. When these are being tested the antisera must be prepared with such meats and not with fresh meat.

Preparation of Antigen. The antigen to be used depends on the type of meat that is suspected. If horse meat is suspected in sausage the antigen for preparing the antiserum will have to be horse meat. If there is some doubt about the type of meat, a number of antisera for various possible meats must be prepared. The rabbit is most commonly used for preparing precipitating sera. The antigen is injected either intraperitoneally, intravenously, or subcutaneously. It may be either the serum from the animal whose meat is suspected or a decoction of the meat itself. The latter is probably more specific. Dumitrescu and Manulescu,²⁷¹ in detecting horseflesh in preserved sausage, injected rabbits every five days with increasing amounts of horse serum starting with five ml. and using progressively 10, 20, 40, 60, and 80 ml. of horse serum. After the third injection, the serum was titrated. The injections were continued until a minimum strength of precipitin of one to 10,000 was secured. This preliminary titration is important since no two rabbits react in the same manner. Consequently it is advisable to determine the titer of the blood and to use more than one rabbit for each antiserum. The blood serum of the animals whose meat is suspected may not be readily obtain-

able and consequently a decoction of the flesh may have to be used. About 30 grams of the meat under examination should be covered with 100 ml. of sterile physiological salt solution. This is then allowed to stand overnight in a refrigerator, after which it should be filtered clear by any of the usual methods. Some technicians advise that this should be adjusted to a neutral reaction and diluted with sterile water until only a slight even turbidity is formed by the addition of concentrated nitric acid. The less the amount of fat in the above protein solution, the easier will it filter. Before injection, the protein solutions should be sterilized by passage through a stone filter. The sterilization of this water extract before injection is very important since the mortality among the rabbits is high anyway owing to anaphylaxis and infection.

Preparation of Antisera. The details for this need not be given here since they are so well stated in books on pathological technic.²⁷² Certain it is, however, that this, like all serum reactions requires careful clean work. After the antisera have been prepared they may be preserved by .1 to .4 per cent of tricresol. The antisera should be active in high dilutions and each serum must be specific for its proteins.

The strength of the precipitin serum should be followed as it is being formed in the rabbit. Hektoen²⁷³ proposed the following combination: Small, perfectly clean, and perfectly clear glass tubes are best, the lumen being about .5 cm. in diameter. In each of a series of such tubes in a rack, is placed .5 ml. of antigen dilution, the first tube receiving the lowest dilution, the next the next higher, etc. (for example 1:500, 1:1000, 1:1500, 1:2000, etc.); there is now introduced by means of a capillary pipette .1 ml. of antiserum at the bottom of each tube, special care being taken to get a precise line of contact between the two fluids. The antiserum also can be run in slowly at the side of the tube; being heavier than the diluted antigen it will go to the bottom of the tube, but the line of contact will not be quite so sharp as when it is introduced at the bottom with a pipette. The tubes which are kept at room temperature are now watched for the formation of a grayish-white precipitate at the plane of contact between the fluids. If a precipitate forms at once in the antigens dilution of 1:1000, the antiserum is strong enough to be used for forensic purposes. An antiserum that forms a precipitate almost at once in thousandfold dilution of antigen usually gives reactions in much higher dilutions—1-20,000, or higher, after a longer time, say twenty minutes."

While the rabbit has been most commonly used, Sutherland²⁷⁴ in India used the fowl. He found that fowl was more reliable than the rabbit. Hektoen, however, advised the rabbit precipitin production since it is abundant in this country. When an antiserum must be prepared against rabbit protein, the fowl may be used. The guinea pig does not yield a strong precipitating serum.

Nötel²⁷⁵ stated that a highly active antiserum was necessary and that from 10 to 12 injections of the antigen should be made. The animals should not be bled until after six days. Fiehe²⁷⁶ gave rabbits four injections of 15 ml. of horse blood every five days. He also stated that powerful antisera were necessary.

Procedure for the Test. This should be carried out only after the antisera have been shown to be potent and specific. In the final test the combinations are so arranged that the procedures and the components are well checked up. Schneider²⁷⁷ suggested the following:

- Tube 1, 2 ml. unknown extract (1-300) + .1 ml. anti-horse serum.
- Tube 2, 2 ml. unknown extract (1-300) + .1 ml. normal rabbit serum.
- Tube 3, 2 ml. horse-flesh extract (1-300) + .1 ml. of anti-horse serum.
- Tube 4, 2 ml. pork extract (1-300) + .1 ml. of anti-horse serum.
- Tube 5, 2 ml. beef extract (1-300) + .1 ml. of anti-horse serum.
- Tube 6, 2 ml. saline solution + .1 ml. of anti-horse serum.

272. Methods for taking blood from experimental animals have been discussed in various books in the fields of pathogenic bacteriology and pathology.

277. Schneider. 1915. Microbiology of Foods. P. Blakiston's Son & Co.

Schneider advises stratifying the immune sera in the tube. They should be kept at room temperature. If "tubes 1 and 3 show a clouding within five minutes and if a definite precipitate forms within thirty minutes, the other tubes remaining perfectly clear, the extract is probably one of horseflesh or the flesh of some other single-toed animal."

According to Dumitrescu and Manulescu²⁷¹ the skin and from one to two mm. of the outer layer are removed from about 20 grams of sausage and the remainder freed as much as possible from fat. This is then ground fine and mixed with nine per cent physiological salt solution to a thick paste and allowed to stand in a refrigerator for 50 hours with frequent shaking. The liquid is then pressed out, centrifuged, and the layer of fat removed. To each 2.5- and 5.0-ml. portions of this decoction are added 25 ml. physiological salt solution, the mixtures being centrifuged until perfectly clear. To four uniform 12-cm. test tubes are added the following solutions:

No. 1. About one ml. of undiluted physiological salt extract of sausage containing horseflesh.

No. 2. Same as No. 1.

No. 3. One drop of horse serum and one ml. of physiological salt extract of the suspected sausage.

No. 4. One ml. of serum from a sausage free of horseflesh.

To each of tubes 1, 3, and 4 is added .1 ml. of seroprotein and to tube 2, .1 ml. of the serum of an untreated rabbit. In tubes 1 and 3, after agitation, a cloudiness appears which slowly increases in 30 minutes to a precipitate. Tubes 2 and 4 should remain clear. This test detects two per cent of horseflesh with an antiserum active in a dilution of 1:18,000. A serum which is active only in a dilution of 1:1000 gives practically no reaction.

The precipitin test is applicable only to sausages which have not been cooked. Cooking, of course, coagulates the protein.

Stokes and Stoner²⁷⁸ in applying the precipitin test to blood used the following technic which may be followed in its application to the detection of foreign proteins:

No. 1. The test proper: Two ml. of unknown solution plus .1 ml. immune serum.

No. 2. Control: Two ml. of unknown solution plus .1 ml. immune serum.

No. 3. Control: Two ml. of diluted blood of that species of animal whose blood is suspected to be present in the unknown solution plus .1 ml. immune serum.

No. 4. Control: Two ml. of unknown solution alone.

No. 4. Control: Two ml. of diluted blood serum of a different species of animal from that suspected to be present in the unknown solution plus .1 ml. immune serum.

These combinations, while devised for blood, may be used for foods, especially proteins, by substituting the physiological salt solution extracts of the meats for the blood serum.

Just as there is a group agglutination between certain bacteria, as with members of the colon-typhoid group, for instance, we also have a "group precipitation" by proteins which come from closely related animals. It is impossible to differentiate between *Escherichia coli* and *Eberthella typhosa* when low dilutions of antisera are used. In the same way, it is impossible to distinguish between proteins and blood from man and the primates. Schneider stated that the proteins from horses and donkeys cannot be differentiated by this test.

Some limitations exist in application of the precipitin test in the food industries. Proteins from animals which are closely related cannot be separated. It may not be needed in the United States, for other methods are available in some cases. It has been useful in Europe where it has helped to detect presence of horseflesh in meat preparations. Dumitrescu and Manulescu,²⁷¹ Nötzel,²⁷⁵ Fiehe,²⁷⁶ Uhlenhuth, Weidanz, and Weder-

278. Stokes and Stoner. 1917. Boston Med. and Surg. J. 3, 65-72.

man,²⁷⁹ Windmuller,²⁸⁰ Weidanz,²⁸¹ Goujoux,²⁸² Schmidt,²⁸³ Uhlenhuth and Weidanz,²⁸⁴ Blanc,²⁸⁵ Saint-Fernin,²⁸⁶ Behre,²⁸⁷ and Baier and Reuchlin²⁸⁸ have discussed the technic in many cases and the results secured with the method. Yoshinaga²⁸⁹ used the test in Japan for detecting frog and other meat in turtle products.

According to Baier and Reuchlin²⁸⁸ drying, pickling, smoking, or preserving of meat does not mask or prevent use of precipitin test. They also used putrid and moldy meat. Bolin²⁹⁰ stated that rabbits immunized to cooked meat had specific precipitins for the uncooked specific protein and at the same time had nonspecific precipitins for cooked meats of different species. Meats held at 15 pounds' pressure for 10 minutes were unsuitable as antigens. He also stated that immature animals were not suitable for precipitin production.

Ferguson, Racicot, and Rane's²⁹¹ Precipitin Test for Determination of Soybean Flour in Sausages. This method was proposed for establishing presence of soybean flour in sausages as well as to show the approximate quantity.

Preparation of Antisoy Serum. Rabbits were immunized according to the method proposed by Glynn. An antigen was prepared by extracting 10 grams of a commercial soybean flour with 100 ml. of five per cent sodium chloride for 12 to 15 hours with intermittent shaking. The extract was filtered through paper and diluted with an equal volume of distilled water. The freshly prepared extract thus diluted was used for the injections. The antigen contained an average of 55.4 mg. of soy protein nitrogen per 100 ml.

Six rabbits were given three courses of intraperitoneal injections of increasing amounts of the antigen. Each course consisted of five injections of 2, 4, 6, 8, and 10 ml., respectively, the injections being given five days apart. A three weeks' rest period followed the fifth injection of the first two courses.²⁹² Nine days after the last injection of the third course the animals were bled from the heart under sterile conditions, 50 ml. being drawn from each, and the blood was pooled. After clotting, the clear serum was removed and filtered through a Berkefeld filter. Before use, it was concentrated to one-half its volume in a cellophane bag in front of an electric fan, since it had been found that this procedure produced a quicker acting serum in the testing of unknown samples.

The rabbits were then placed on a definite injection-bleeding schedule. Five days after the bleeding an injection of 10 ml. of the antigen was given, and on the 9th day following the injection 50 ml. of blood were taken. This procedure of alternate injec-

292. An antigen prepared with two per cent urea solution as the solvent in place of the five per cent NaCl was used during the third course on three of the rabbits showing the lowest titer at the end of the second course. It was noted that two per cent urea has approximately the same solvent power for soy protein as has five per cent NaCl, and that it can be injected full strength without irritation. By this means, approximately double the amount of soy protein was injected into these low-titered rabbits during the third course in an effort to determine whether or not a more potent serum could be obtained. The results show that such an antigen produced a serum equal in potency to that of the other rabbits. Further study of the antigen prepared with urea solution is anticipated.

tions and bleedings was continued over a period of several months, and it resulted in the accumulation of a large quantity of serum of more or less constant titer.

The strength or titer of the serum in terms of soybean flour protein is based on the method proposed by Glynn,²⁹³ with variations as to the time and temperature of incubation. The actual method of titration is as follows:

Extract 1 gram of soybean flour with 100 ml. of 5% NaCl for 1 hour, with intermittent shaking, and filter through paper. Set 10 Wasserman-size test tubes in a rack and place 1 ml. of the original undiluted extract in the first tube and 1 ml. of a dilution of the extract made with .5% NaCl in each of the remaining tubes so that each succeeding tube has one-half the concentration of extract.

Add .2 ml. of serum to each tube, shake to mix, and incubate in a 56°-60°C. water bath. Examine every 10 minutes for the presence of a distinct flocculating precipitate. (The tube farthest to the left showing the characteristic precipitate is the so-called “indicator” tube. The tubes to the left of the “indicator” tube will remain uniformly cloudy, whereas several of those nearest to it on the right will show the precipitate in decreasing amounts, with those on the extreme right remaining cloudy. The serum with the highest titer is that in which the “indicator” tube is farthest to the right, or in other words, in which a given amount of serum will form a precipitate with the least amount of soy protein.)

In the actual use of the serum for the determination of soybean flour in sausages, it was found that the best results were obtained when the serum had been standardized against sausage of a known soybean flour content. It was noted that an “indicator” tube, in the case of an extract containing both soybean flour and sausage, is a different tube from that observed in the case of an extract prepared from an equal quantity of the flour alone, in the same dilution. It is believed that the presence of the meat proteins, added salt, milk powder, curing agents, etc., may tend to shift the zone of optimal precipitation as has been shown for other serological procedures. The method followed in this standardization is identical with the method for testing an unknown sample.

Procedure for the Test. Pass sample of sausage of the frankfort type known to contain no soybean flour through a sausage grinder three times. Place 25 grams of the ground material to which is added .25 gram of soybean flour and 100 ml. of 5% NaCl solution in a bottle, stopper, shake in a machine for 1 hour, and filter through paper. (The sausage, based on the moisture determinations on a number of samples, is assumed to contain 50% of moisture; 25 grams of sausage would therefore, provide ca. 12.5 ml. of water, which when added to the original 100 ml. gives a total volume of 112.5 ml. Since .25 gram of soybean flour is therefore extracted by 112.5 ml. of solution, the dilution of the extract is 1:450. The dilutions and amounts of extract and serum used are shown in the set-up of a typical test illustrated in the following table. Incubate

TUBE	1	2	3	4	5	6	7	8	9	10
Dilution	1-450	675	900	1350	1800	2700	3600	5400	7200	10,800
Antigen (ml.)	0.8	0.8	0.8	0.8	0.8	0.8	0.8	0.8	0.8	0.8
Serum (ml.)	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2	0.2
1st Reading	Cl	Cl	Cl	Cl	+	+	+	±	Cl	Cl

Tube 5 is the “indicator” tube. Its dilution is 1:1800
1800 ÷ 900 = 2% soybean flour.

2nd Reading	+	+	+	±	±	Cl	Cl	Cl	Cl	Cl
-------------	---	---	---	---	---	----	----	----	----	----

Tube 1 is positive. This tube or a tube representing a lower dilution than 1-450 is the “indicator.” The per cent of soybean flour cannot be greater than
450 ÷ 900 = 0.5%.

3rd Reading	Cl	Cl	Cl	Cl	Cl	Cl	+	+	+	+
-------------	----	----	----	----	----	----	---	---	---	---

Tube 7 is the “indicator” tube. Its dilution is 1:3600
3600 ÷ 900 = 4% soybean flour.

293. Glynn.

for 1½ hours and read.²⁹⁴ (The tube farthest to the left showing a distinct precipitate or flocculation at the end of 1½ hours is the "indicator" tube. Assuming that this is Tube No. 3, for example, this would mean that the lowest dilution at which a sausage containing 1% of soybean flour gives a precipitate under the conditions of the test is 1:900 with the serum that is being standardized.) In testing sausages of unknown composition, the dilutions are made up as if the sausage contained 1 per cent of soybean flour. (It will actually contain no soybean flour or else a multiple of 1 per cent.) For convenience the tubes may be labeled left to right with the same dilution numbers as if the sausage contained 1 per cent; i.e., 1-450, 675, 900, 1350, 1800, 2700, 3600, 5400, 7200, and 10,800.

Suppose that in the testing of an unknown sample, the "indicator" tube is No. 3. This means that this tube contains the same quantity of soy protein as did Tube No. 3 in the standardization test. The sample used in standardization contained one per cent of soybean flour. Therefore, since the dilutions of corresponding tubes in the two tests are the same, the unknown sample must also contain one per cent. But suppose that Tube No. 5, in the unknown sample, had been the indicator instead of Tube No. 3. Since Tube No. 5 contains double the dilution of Tube No. 3, or one-half the amount of soy protein, it follows that the original sausage must have contained two per cent of soybean flour. If Tube No. 8 had been the indicator, then the original sample contained six per cent, since there is only one-sixth the amount of soy protein in Tube No. 8 as in Tube No. 3.

POULTRY

The nature of the flesh of fowls and the necessity of shipping it long distances have made it imperative to understand changes which it may undergo. Cold storage above freezing has been much used for preserving fowls, although recently freezing solid has been introduced. Pennington²⁹⁵ stated that changes which take place in a fowl in three weeks in the chill room are about equal to those which take place in a house refrigerator in from five to seven days. When fowls were stored below freezing, loss of flavor was reported after nine months. McBryde and Powick²⁹⁶ reported that bacteria and molds were of no consequence during storage because they did not penetrate the tissues. Wiley²⁹⁷ and his colleagues stated that the tissue of cold-storage fowls contained many bacteria as against none in the flesh of fresh fowls. Pennington had found bacteria, but they were fewer as storage temperatures approached 0°C.(32°F.).

Poultry has been shipped either drawn or undrawn. Comparative observations on the quality of both types were made by Pennington²⁹⁸ and Brown.²⁹⁹ Pennington's work was carried out under commercial conditions and indicated that in the process of cleaning the flesh becomes heavily seeded with bacteria. Undrawn fowls are not so heavily seeded with bacteria. Brown gave more attention to the activity of bacteria on cold-stored fowls. Poultry stored at a temperature of -15 to -25.6°C.(5 to -14°F.) undergo no bacterial spoilage. These temperatures destroyed many bacteria, but not the more resistant species. When the fowls were allowed to

294. Because of the inherent differences in the rate at which rabbit serum will flocculate, it was found that this incubation time permitted a complete reaction.

thaw, the surfaces became moist and bacteria were thus able to grow. Drawn chickens placed in cold storage showed many more bacteria than undrawn.

Results quite similar to these were also reported by Boos.³⁰⁰ When drawn and undrawn fowls were taken from cold storage and exposed to a temperature of 20°C.(68°F.), the undrawn birds showed better keeping qualities. An improved method of drawing was said to yield fowls showing "perfect keeping qualities," while the undrawn fowls underwent rapid decomposition.

Bissell³⁰¹ stated that turkeys and presumably other domestic fowls or game, were not detrimental to health if held for a year in cold storage. He believed, however, that they should be carefully prepared.

Studies on deterioration of chilled, dressed poultry were made several years by the Department of Agriculture of the Dominion of Canada. While it is generally believed that bacteria cannot grow below -10°C.(14°F.), various species of cold-tolerant organisms are known to develop well below freezing. This problem was studied with 144 birds which were precooled to -1.1°C.(30°F.) and then packed regularly in a box. These birds were examined when freshly packed and after two, four, six, and eight weeks. Bacterial counts were made of the skin and breast tissue of each bird. A notable increase in the average bacterial numbers on the skin surface at temperatures of -1.1 and 0°C.(30 and 32°F.), more pronounced at the former, was noticed. It was observed that the birds acquired a surface odor before there was any decomposition of, or significant increase of bacteria in, the muscle tissue examined. Lochhead and Landerkin³⁰² believed that the deterioration of dressed poultry at 30 and 32°F., to the point where the birds acquired a noticeable odor, is essentially a surface spoilage owing to bacterial growth. With the birds held at 0°C.(32°F.), this initial sign of spoilage was first observed after four weeks, being apparent with those stored at -1.1°C.(30°F.) after six weeks. Even a difference of two degrees in storage increased the keeping ability of the birds. Compared with the skin, the bacterial content of the breast muscle was very low. During the period of the test these changes were insignificant.

The predominant bacteria on the skin were representative of the genera *Micrococcus*, *Flavobacterium*, and *Achromobacter*. Comparison was also made with birds held at -2.2°C.(28°F.). Bacterial development was noted at this temperature even though the birds were frozen at this temperature.

The susceptibility of cold-stored poultry to decomposition after removal from refrigerated storage, as compared with the freshly killed product, was also studied. Bacterial decomposition appeared to be most rapid in frozen poultry while that of chilled poultry meat was intermediate between the frozen and freshly killed product. The relative decomposition of chilled

and frozen meat may be expected to vary with the time and temperature of storage and the manner of freezing and defrosting.

Mallmann³⁰³ found that formation of slime on squab ducklings was caused by aerobic, nonsporeforming bacteria resembling *Bacillus mesentericus*. The carcasses were found to be infected by utensils and dressing rooms of the packing plant. Pure cultures of the organism isolated reproduced the spoilage. Slime formation was delayed by addition of sodium hypochlorite to the storage tanks and by dipping the dressed ducklings in saturated salt brine.

CHAPTER 22

MICROBIOLOGY OF EGGS AND EGG PRODUCTS

Eggs and egg products are important articles in the diet. They are perishable and must be handled carefully lest they assume characteristics which render them undesirable. The problem is quite difficult since a large part of the lay occurs in the spring. This makes it necessary to hold the abundance of these months against the need of others. Furthermore, the mass of production must take place in rural areas, making it necessary to ship eggs for long distances to urban centers. In view of the problems which are connected with shipment and storage, it is desirable to know as much as possible about the chemistry and bacteriology of eggs. Moran and Piqué¹ discussed with considerable completeness the storage of eggs. Microbiological problems have been presented in a report of the Food Investigation Board of Great Britain by Haines.² Another discussion of the egg problem, by Perard,³ is a special thesis on prompt handling of clean, fresh eggs. Circular 583 (1941) of the U. S. Department of Agriculture is also very good.

The oviduct of the hen is located in the rear part of the body cavity. The yolk is the first part to develop and this takes place in the ovary which may contain a large number of minute yolks. Each is contained in a sac, or follicle, through which it secures its nourishment while developing. After development, the yolk, enclosed in its vitellin membrane, escapes from the yolk sac and descends through the oviduct. If fertilization occurs, it occurs soon after the egg has entered the oviduct and before any albumen is deposited about it. About 40 per cent of the albumen is said to be laid down as the yolk passes through the upper half of the oviduct. After passage through this albumen-forming region, it reaches the isthmus where the shell membranes are added with about 10 to 20 per cent more albumen. The uterus is then reached, where the remainder of the shell is added. During passage through the vagina, just before its expulsion from the cloaca, it probably receives the outer gelatinous coating on the shell. (See Benjamin.⁴)

Schneiter⁵ classified eggs and egg products into the following groups:

- | | | |
|----------------|-------------------------|-------------------------|
| 1. Shell eggs | 3. Dried eggs | 4. Frozen eggs |
| | (a) Albumen or whites | (a) Albumen or whites |
| 2. Broken eggs | (b) Yolk | (b) Plain yolk |
| (a) Whole eggs | (c) Whole or mixed eggs | (c) Sugar yolk |
| (b) Egg whites | | (d) Salt yolk |
| (c) Egg yolks | | (e) Glycerine yolk |
| | | (f) Whole or mixed eggs |

Grading of Eggs. This is essentially a commercial problem in which bacteriology has not had a role. In commerce, eggs are usually graded by candling, a process which is to the egg industry what sanitary inspection is to milk and water. Frazier,⁶ Stiles and Bates,⁷ Moran and Piqué,¹ and the California State Board of Health⁸ have devised systems for grading eggs. In the United States the Federal Government¹⁰⁹ puts eggs into four grades: U. S. Special (retail Grade AA), U. S. Extra (retail Grade A), U. S. Standard (Grade B), and U. S. Trade (Grade C). Eggs with dirty shells are graded U. S. Extra Dirty, U. S. Standard Dirty, and U. S. Trade Dirty, according to their quality. Complete descriptions of these grades have been published by the U. S. Department of Agriculture in Circular 583, published in 1941. Moran and Piqué¹ reported the grades in use in England. Since none of these grading systems use bacteriological criteria, they will not be reproduced here.

“Leakers” and “dirties” are problems in the egg industry. Leakers permit their contents to run out, wherein bacteria develop in great numbers. The heavily seeded material may then act as an inoculum when it reaches the shells of sound eggs. Furthermore, the types of organisms will be those which are able to develop in the egg.

Dirties appear during wet weather and sometimes during hot weather when moisture from the hen's body allows more dirt to adhere to the shell. Many of these are used for local consumption or for drying since they do not keep well. In examination of eggs with dirty shells, Pennington⁹ secured widely divergent results. The minimum number of bacteria was 400 and the maximum number 1,500,000 per gram at 20°C. (68°F.). The number of *Escherichia coli* varied from 10 to 10,000 in six samples. It has been reported by many investigators that dirty eggs do not keep well. Often these eggs are washed but this process lowers the keeping quality since it removes the delicate membrane or film of mucous on the surface of the shell.

Since bacteria develop in eggs in different ways, different kinds of rot are known. The fertile egg is much more liable to rot than is the sterile egg. Benjamin⁴ described the following rots: *White rots* are common and often called water rots, sour, or addled eggs. They represent the first stages in bacterial decomposition. Such eggs have an enlarged air cell before the candle and a mixed interior. When opened, they are usually a light yellow in color and watery. *Mixed rots* represent a more advanced stage of decomposition and are characterized by thin interiors; in the open conditions, they give off an odor of hydrogen sulfide and sourness. The yolk is rarely intact. *Black rots* are eggs in which the contents are very dark and may be easily shaken about in the shell. When opened the odor is much like that of hydrogen sulfide. In appearance, the contents are mixed and very watery.

9. Pennington *et al.* 1914. U. S. Dept. Agr., Bur. Chem. Bull. 51.

Black rot of eggs was reported by Bohart¹⁰ to result from reduction of sulfur compounds with consequent formation of hydrogen sulfide. She inoculated sterile egg white in culture tubes with anaerobic and facultative anaerobic bacteria from black rot eggs. No blackening resulted even after incubation for 60 days. However, *Clostridium sporogenes* and *Clostridium putrificum* were isolated from eggs which underwent black-rot spoilage after inoculation under aseptic conditions with facultative anaerobic proteolytic bacteria. Continued study seemed to indicate that practically all anaerobic proteolytic bacteria will produce black-rot spoilage if given the right conditions. Bennetts¹¹ observed an organism of the genus *Serratia* as the cause of putrefaction of eggs.

Kuhl,¹² from the examination of large numbers of eggs, concluded that for trade purposes the following would be a good classification of commercial eggs: fresh eggs, those up to eight or 10 days old; eggs not over four weeks old; cooking eggs, any offered for sale which are not spoiled. Such a classification would be difficult to apply by food-control officials. Furthermore, it would not always accomplish the results that systems of grading insure. The conditions which obtain during the storage of any food product must also be considered. Age alone is of little value as a criterion of quality.

Fresh eggs are usually desired. This need not indicate that eggs which are not newly laid are undesirable. It is difficult to secure a satisfactory definition of the term "fresh," as applied to eggs. It is equally difficult to find methods for determining whether an egg conforms to the definition after one has been adopted. Schweizer¹³ proposed a method based on determination of the hydrogen-ion concentration. A hole was made in the egg, one ml. egg white pipetted off and mixed with one ml. indicator and five ml. isotonic sodium chloride solution for colorimetric pH determination. Phenolphthalein and m-nitrophenol were used as indicators. Eggs held at 8°C.(46.4°F.), 20°C.(68°F.), and 28°C.(82.4°F.) showed an increase of pH from 7.7 to 9.5 in 10 days, because of loss of carbon dioxide. Eggs treated with water glass or lime water did not appreciably increase in pH. Eggs stored in air showing a pH of 9.4 or over must be judged as over eight days old. Another method was proposed by Zach,¹⁴ who believed that the luminescence of eggs increased with age. However, it was stated that the storage temperature of the egg had to be known, for luminescence became greater at higher storage temperatures. Such a method would probably not be adaptable to routine work.

Molds in Eggs. Eggs which are not stored under proper conditions frequently develop molds. The hyphae usually extend toward the air cell and produce sufficient growth to give what is known as a mold spot. To prevent this deterioration, eggs must be stored under good conditions.

14. Zach. 1929. Mitt. aus dem Geb. der Lebensmtl. Untersuch. u. Hyg. 20, 209-215.

Smith¹⁵ confirmed this by storing a few eggs at relative humidities of 90, 95, 98, and 100 per cent and at temperatures of 0, 5, and 10°C. (32, 41, and 50°F.). Mold development, as would be expected, was found to be greatly influenced by these factors. At a temperature of 10°C. (50°F.) and a relative humidity of 100, mold growth appeared in five days. Lower humidities and lower temperatures delayed development of the molds which were naturally present in the eggs. Besides the molds which may be present within the egg, there may be others on the shell. These may be numerous and may cause trouble if the eggs are not stored in clean, dry places. Tomkins,¹⁶ by means of a washing process, found between 200 and 500 spores per egg. When eggs are held in a humid environment these spores develop and cover the egg shell with dense growth. At lower humidities less mold growth occurs but the eggs may assume a musty odor. While most molds on the exterior of the egg develop only on the shell, a few have been known to penetrate the shell membrane.

In 1864, Mosler¹⁷ stated that sound eggs could be infected by *Penicillium glaucum* and *Mucor mucedo*. Zimmerman¹⁸ reported the isolation of *Melrosporium verruculosum*, *Torula ovicola*, *Penicillium glaucum*, and several other microorganisms from decayed eggs. Zopf¹⁹ frequently isolated *Hormodendron cladosporioides* from eggs. Gueguen²⁰ isolated *Cladosporium herbarum*. Resistance to molds, according to Brtnik,²¹ might be exhibited for three months. Consequently, he believed that there was need for a careful inspection of establishments handling eggs. Kossowicz²² found that old eggs are more susceptible to mold invasion than are fresh eggs; this is probably to be expected. Postolka²³ confirmed this opinion. Marked growth of molds took place after either natural or artificial infections in the testacea but rarely in the yolk. Natural infection was caused by *Penicillium glaucum* and *Cladosporium herbarum*. Under experimental conditions, almost any mold will attack and penetrate the egg. Postolka stated that with even great infection with molds, no putrefaction takes place. Considerable study was given to this question by Moran and Piqué,¹ who examined eggs encountered in stores. Too many data were reported to reproduce here. However, molds belonging to the genera *Sporotrichum*, *Penicillium*, *Cladosporium*, *Alternaria*, and others were reported. In a study of a new type of mold spoilage of shell eggs, James and Swenson²⁴ isolated two molds, *Penicillium* and *Cladosporium*. Inoculation experiments showed that eggs shipped in seasoned wooden cases developed the spots to a negligible extent. Eggs shipped in cases of unseasoned wood from California to New York showed the development of mold to a marked degree.

Cladosporium herbarum is apparently one of the most troublesome fungi causing mold spoilage of eggs. Experiments by Weston and Dillon²⁵ revealed that it developed rapidly on eggs and in less than 14 days penetrated the shell membranes. They compared the size of pores in the shell with the diameter of hyphae and found that the latter could easily find their way into the egg. Several hyphae entered a pore together and penetrated directly through the air spaces. While the albumen in affected eggs was not contaminated after one month, the membranes were severely attacked. Baeza²⁶ also isolated several different fungi from eggs. Species of the genera *Hormodendron* and *Alternaria* were most common. Infection from contaminated material was believed to take place after laying.

The importance of humidity in mold growth on eggs was again shown by Sharp and Stewart.²⁷ A dark mold developed on eggs stored at 1.1°C. (34°F.) for three months or more at relative humidities between 96 and 100 per cent. Slight development occurred under the same storage conditions with a relative humidity of 90 per cent. The hypothesis was proposed that under this last set of conditions, failure of the mold to develop luxuriantly might be due to a restriction of the food supply as controlled by moisture. White growth of mold on the shell increases mold infection of the interior of eggs if they are held for a sufficiently long time. While a few species of fungi have been most commonly isolated from moldy eggs, Mallmann and Michael²⁸ recognized that different species might be the cause. Molds were said to originate from handling and packing after the eggs had reached the storage plant. Mallmann and Michael repeatedly isolated representatives of 10 genera from eggs and packing material; the majority belonged to the genus *Penicillium* but no one species predominated. Not all of the molds penetrated into the egg interior during cold storage. Only two genera were isolated from the interior of eggs, most of which belonged to *Penicillium*; four strains of *Hormodendron* were isolated.

These investigators also made a few experiments to determine whether a mycostat could be used for preventing mold development. After considerable study they recommended sodium pentachlorophenate in .4-per cent solutions to be incorporated in the fillers, flats, and cases. They could detect no difference in quality of eggs which were stored in strawboard containing this compound. Importance of egg containers as sources of molds was indicated by results of investigations by Toop.²⁹ After storage for some eight months at -6°C. (31°F.) and at a relative humidity of 87 per cent, six per cent of the cases were found to be affected with mold. Various factors, such as the type of wood and age of the case, greatly influence appearance of mold.

Enzymes in Eggs. Rullmann³⁰ found catalase in eggs which were bacteria free. The amount had no relation to the age and was about equal in

the yolks and whites. In putrid eggs the amount was so large that the sample had to be diluted. Pennington and Robertson³¹ studied this question, using eggs of known history. They experimented to determine the presence of pepsin, trypsin, lipase, catalase, and reductase. Lipase content increases from a little in a fresh egg to a large amount in a stale egg. The catalase content of a fresh egg was found to be variable.

Factors Influencing Bacterial Content of Eggs. A study of this question involves two points, the first being the entrance of bacteria before the shell is put down, and the second, the contamination after laying, owing to improper handling, etc. While the first point has been studied, the data are not convincing. Mauer,³² in quoting the work of Pernot,³³ stated that infection of the yolks, even in the normal ovary is possible. Zimmerman,³⁴ Abel and Draer,³⁴ Cao,³⁵ McClintock,³⁶ Poppe,³⁷ and others maintained that the oviduct is not sterile. Contradictory to this are the data of Horowitz³⁸ and Rettger.³⁹ Obviously, under abnormal conditions the oviduct may be infected. This has been found to be true with *Salmonella pullorum* (*Bacillus pullorum*) and the white diarrhoea of chicks. Bushnell and Mauer⁴⁰ pointed out that there are factors which lower the vitality of the hen and render her unable to resist invading bacteria. Hadley and Caldwell⁴¹ thought that the preponderance of yolk infections indicated that bacteria are present in the ovaries of the hen. Lamson⁴² reported bacteriological studies with reference to the cause of decomposition and sources of infection of eggs, the part played by temperature, and precautions to be observed in preserving eggs. Dissections of hens were made by Lamson for examination of the ovary and oviduct. Bacteria were present in the oviduct of the hen, even in the upper portions, so that an egg may be infected in the earlier stage of its formation, particularly at the time when the white or albumen is secreted. A diseased condition of the ovary of the hen may cause infection of the eggs. Eggs may be infected after they have been laid, as it is possible for the bacteria to pass through the pores of the shell. Moisture plays a part in such infections; while the fresh egg is covered with a normal mucilaginous coating, it is difficult to infect if kept in a dry place. Infection is not difficult, however, when the egg is moist. Many egg shells are defective, caused by not feeding the hens a sufficient amount of shell-forming food. Eggs are liable to be infected soon after they are laid. Nine species of bacteria were found in one nest, hence Lamson thought that nesting material was a great source of infection; if it has been allowed to remain unchanged for a long time it becomes foul and teems with bacteria.

Whatever the means of infection, larger percentages of the July, August, and early September eggs were infected or contained a greater number of bacteria (at a time when they were called fresh) than the eggs of the other months of the year, particularly when compared with eggs laid during the months of April, May, and June. This corroborated the opinion of egg packers, who invariably prefer April, May, and June eggs to those produced during the other months of the year. The fact that an egg contains bacteria does not mean that it is worthless. The question is mainly whether or not they are present in large numbers, and if present in small numbers, whether or not they are likely to multiply. Bacteria which are commonly found in eggs do not multiply at low temperatures. An egg that is kept at $1.1^{\circ}\text{C}.$ ($34^{\circ}\text{F}.$) is safe from decomposition. Repeated experiments have shown that the rapid growth of bacteria does not occur until the temperature is raised over $13^{\circ}\text{C}.$ ($55^{\circ}\text{F}.$). While there is some growth at temperatures lower than $13^{\circ}\text{C}.$ ($55^{\circ}\text{F}.$), it is very slow. At the temperature of $37^{\circ}\text{C}.$ ($98.6^{\circ}\text{F}.$) the bacteria in eggs multiply rapidly. In order to demonstrate the rapid multiplication of bacteria resulting in decomposition a dozen (January) eggs were taken, in six of them small holes were made, and into each egg bacteria from a rotten egg were introduced on a platinum loop. These holes were sealed with wax and the eggs thus infected, together with the six untreated eggs, were placed in an incubator running at a temperature of $43.3^{\circ}\text{C}.$ ($110^{\circ}\text{F}.$). In 48 hours, the six eggs which had been infected were so badly decomposed that they were very offensive, and the remaining six showed no changes in them. Tice⁴³ reported results of a chemical and bacteriological examination of some eggs of known history which seemed to indicate that eggs laid under clean conditions and stored in cases in a warehouse, in such manner as to be protected from dirt and excessive moisture, could be kept for as long as 10 months, without showing appreciable evidence of putrefactive decomposition. Mauer³² published a lengthy study of various factors which affected the bacterial content of eggs. Eggs were examined for the presence of *Escherichia coli*, the work being undertaken as a part of a study of the economic aspects of the egg industry, and particularly with reference to the deterioration of frozen and desiccated eggs. Sixty fresh, clean eggs from 30 different hens collected twice a day from trap nests, 50 eggs obtained from local farms, and 25 dirty eggs obtained from a packing house were used. The dirty eggs were at least three weeks old and were fairly covered with droppings. The colon bacilli were absent from the contents of all the eggs studied, from the shells of about 77 per cent of the clean eggs, and from 82 per cent of the farm eggs but were found on the shells of all the dirty eggs.

Experiments were made under a variety of conditions, including low temperature, with eggs smeared with feces and egg, and with a suspension of *Serratia marcescens*. In general, the results indicated that the microorganisms under consideration did not penetrate the unbroken shells of the eggs. These data were contrary to those published by others.

43. Tice. 1911. New Jersey Bd. Health, 35th Ann. Rpt., p. 275.

Experiments also showed that concentrated egg albumen did not exercise bactericidal action upon *Escherichia coli*, a conclusion in harmony with that of other investigators. Indeed, the presence of large numbers of colon bacilli in frozen and desiccated eggs would be impossible if the egg possessed bactericidal properties for this organism. It seemed, therefore, that the only explanation for the absence of *Escherichia coli* from fresh eggs and from the oviduct was the lymphoid structure of the mucosa of the oviduct. This probably causes the removal, by leucocytic activity, of colon bacilli which have reached the oviduct, together with other intestinal organisms.

Mauer concluded that fecal matter is the source of many of the colon bacilli often present in egg preparations. The bacterial content of canned eggs may be greatly reduced by separating only clean eggs. All soiled eggs which either directly or indirectly might give rise to fecal contamination of the egg meat, should be utilized without separating the white from the yolk.

Results of investigations since the above reports were published have not changed the situation. Andresen⁴⁴ and Zagaevskii and Liutikova⁴⁵ observed microorganisms in eggs, the degree of infection being determined largely by conditions under which the eggs were handled. The latter investigators found eggs to be more sterile than other workers have found.

Chinese Eggs (Pidan). Such eggs appear regularly in the dietary of the Chinese. They are prepared by placing fresh eggs in a mixture of ashes, lye, earth, rice hulls, and lime. They are left for about a year. Bacteriological investigations by Dold and Meiling⁴⁶ showed the presence of *Bacillus subtilis* and other members of this group. The flora seemed to be quite extensive in that many different kinds of bacteria and other lower fungi were found. Different names are given these products, such as pidan, houeidan, and dsaoudan. Pidan is made by packing the eggs in a mixture of salt and ashes. The other products are made in a similar, though not identical, manner. Hanzawa⁴⁷ isolated a number of bacteria but unfortunately did not study them at great length. Tso⁴⁸ stated that Chinese preserved eggs, or "pidan," are produced on a commercial scale from fresh ducks' eggs and are, perhaps, as much relished by the Chinese people as cheese is in Western countries. In preserving, each egg is coated with a layer about seven millimeters thick of a mixture containing pure soda five parts, burned straw ash 25 parts, table salt four parts, slaked lime 40 parts, and boiling water 26 parts. This again is covered with rice husks to prevent sticking. The eggs are laid in earthenware jars and sealed with wet clay for a month. By that time both the white and the yolk are coagulated. The white has turned dark brown and the yolk is greenish gray with concentric rings of different shades of gray. These eggs are marketed with their coverings on, and are usually consumed within six

months of production. The taste of these eggs can only be very imperfectly described as somewhat caustic and piquant, and the odor is largely ammoniacal. In eggs produced in this manner there was, according to Blunt and Wang,⁴⁹ a marked increase in the ash content and the alkalinity of the ash. There was a partial decomposition of the proteins and the phospholipoids, resulting in excessive production of free ammonia and in a diminution of the yolk fat. It was believed that these characteristic changes were brought about by the combined action of bacteria and enzymes, as well as by the alkali preservative.

While the data from Zörkendorfer's⁵⁰ experiments may not be directly pertinent to the subject discussed in this paragraph, they are of indirect interest. He examined a large number of spoiled eggs in order to determine the number of bacteria present and their connection to spoilage. Many types were found, some of which, when grown in pure culture and inoculated into fresh eggs, caused them to spoil in a very short time. These bacteria were arranged in two groups: (1) those which formed hydrogen sulfide, and (2) those which caused the appearance of a greenish-blue color.

Rot of Eggs. Such eggs, of course, are not used for human consumption but are either discarded or sold for industrial purposes. Various microorganisms have been isolated. *Bacillus fluorescens liquefaciens*, *Micrococcus roseus*, and *Staphylococcus aureus* were isolated as causes by Pavarino.⁵¹ Anaerobic bacteria were believed to be the main cause of rot by Bohart.¹⁰ Nearly all of the anaerobes which she tried would produce the decomposition if given long enough time and the right conditions of temperature and humidity.

Another fungus, *Proteus melanovogenes*, was reported by Miles and Halnan⁵² to be the specific cause of black rot in eggs which had been imported into England. This organism produced black rot experimentally when introduced into normal eggs. It apparently penetrates normal egg shells. The organism was found in soil and manure in England. According to Haines,⁵³ the shell of an egg may be heavily infected with a heterogeneous flora, including members of the genera *Proteus* and *Pseudomonas* which are capable of rotting eggs. Haines grouped the different rots into black rot, red rot, green rot, and a miscellaneous group. Black rots were believed to be almost entirely due to strains of *Proteus*, but some stains of *Pseudomonas* cause blackening. Red and green rots are caused by particular stains of *Pseudomonas*. Atypical strains of coliform bacteria produced a fish odor.

Green rot of eggs, observed by Platt and Anderson,⁵⁴ was found to be due to a species of *Pseudomonas* and a proteolytic enzyme which causes a liquefaction of the egg contents. On candling the entire egg interior appeared green, the yolk being a little darker than the white.

Permeability of the Shell. The shell about the egg may be regarded as a semipermeable membrane and, therefore, not resistant to bacteria. Wittich reported the infection of eggs by molds. Wilm⁵⁵ succeeded in infecting eggs with *Vibrio comma*. When the eggs were covered with a broth culture, the organisms passed through the shell in from 15 to 16 hours. Golokow,⁵⁶ Piorowski,⁵⁷ Lange,⁵⁸ and Poppe³⁷ demonstrated the same thing with other bacteria, both pathogenic and nonpathogenic. Opposed to this work is that of Mauer,³² Hoppert,⁵⁹ Sachs-Müke,⁶⁰ Zörkendorfer.⁵⁰ Kossowicz⁶¹ showed that *Bacillus proteus* penetrated the shell very easily. Such data given above suggest the ability of bacteria to penetrate the shells of eggs and thus emphasize the necessity of storing eggs under sanitary conditions. Kossowicz reported that contamination of the egg by microorganisms may occur while in the ovarian duct, but not after it is laid until age causes loss of resistance. No organisms had entered eggs four weeks old; only *Cladosporium herbarum* had entered after eight weeks, *Phytophthora infestans* after 12 weeks, and *Rhizopus nigricans* after five months. The germicidal power of the albumen decreased rapidly with age. In addition to his own work, Kossowicz summarized data from a large number of experiments of others. In his own experiments he reported that a large number of fresh eggs were held from two to three days at temperatures of 20 to 30°C. (68 to 86°F.), and their contents were inoculated into various culture media. With very few exceptions these eggs were found to be sterile. Experiments in which eggs were exposed to various kinds of bacteria under conditions corresponding closely to those under which eggs are often stored in the home, in transportation, and in the trade showed that bacteria could easily penetrate the unbroken shell of the egg and cause decay. This was especially true of the very common putrescible organism, *Bacillus vulgaris*. It was also shown by similar experiments that molds could penetrate the shell under conditions in which moisture and temperature played an important part. At high temperature *Cladosporium herbarum*, and at low temperature *Penicillium glaucum*, are the most active organisms which cause molding of eggs. The shells of old eggs were said to be more easily and quickly penetrated by the molds than those of fresh eggs. Some yeasts were also found to penetrate. Eggs, the shells of which were soiled by the contents of either fresh or decayed eggs, were found to be more susceptible to the invasion of microorganisms. An extended discussion was given of the various methods employed for preservation, from which the author drew the conclusion that the most suitable method is cold storage in rooms which have been filled with carbon dioxide or else packing the eggs in milk of lime or in water glass. Kossowicz⁶² later reaffirmed his contention that bacteria could penetrate the egg shell in refutation of the

claims of Rullmann,³⁰ who did not admit it. The latter claimed never to have observed the penetration of bacteria into eggs the shells of which were intact.

Pennington⁶³ reported a comprehensive investigation of the bacterial content of eggs, the number found and listed being 36 varieties per 100 eggs. In the 57 experiments, 18 had a decidedly greater number of bacteria in the yolk; 11 had the majority in the white and 21 had an almost even distribution; seven were sterile. Both Plymouth Rock and Leghorn eggs were used, and spring and autumn, fertilized and unfertilized, eggs were compared. According to Pennington, the differences in bacterial content which were observed depend upon breed and the conditions under which the eggs were laid as well as the season. In general, the autumn eggs contained a greater number of bacteria than the early spring eggs. That perfectly fresh eggs from healthy hens may contain bacteria is a generally recognized fact. That they are sometimes sterile is also admitted. Whether the organisms enter the egg during its passage down the oviduct or whether they penetrate the shell either at the time of laying or afterward are questions on which opinions are contrary. The fact that certain pathogenic organisms characteristic of fowls, as vibrios of chicken cholera, have been found in the egg argues for infection in the oviduct, as does the presence of foreign bodies, such as small insects; while the trade experience indicates that organisms can enter through the shell.

As to the manner in which bacteria get into eggs, the experiments of Zörkendorfer⁵⁰ indicate that neither the outer shell nor the membrane next the shell are impervious to bacteria. Fresh eggs were inoculated with different forms of bacteria by placing them on the outside of the shell. After a few days colonies of these bacteria were found growing on the inside of the shell. Fresh eggs were also laid in bouillon cultures, and after a few days the bacteria contained in the bouillon were recognized in the egg. In other trials eggs were blown, the shells filled with nutritive gelatin, and the ends sealed up with paper. These artificial eggs were then sterilized in a steam bath, after which they were placed on a mass of egg which had become putrid. When, after a few days, the shells were removed without disturbing the gelatin, a number of colonies of bacteria were found on the side next to the spoiled egg. These colonies were separated from one another, indicating, as in former trials, that the bacteria enter the shell at particular places. Such experiments are open to criticism. They would have to be made with the greatest of care.

Some practical observations were made bearing on the keeping of eggs. It was found that a moist atmosphere was favorable to spoiling, probably because moist air was more favorable to the growth of bacteria on the outside of the shell. A low temperature was unfavorable but was not proof against spoiling, since nearly all of the bacteria found grew in a refrigerator, although slowly. The majority of the bacteria found were killed by a temperature of about 50°C.(122°F.). In view of this it was suggested that heating eggs one or two days at that temperature and then storing

63. Pennington. 1909. J. Biol. Chem. 7, 109-132.

11. 500 14054 pp 923 - 980

them in a dry place would probably be effectual in most cases, although this does not entirely preclude the action of bacteria which might get on the outside of the shell. The most effectual precaution suggested was that of excluding the supply of oxygen which the bacteria require for growth. This is often done by placing the eggs in lime water, but with unsatisfactory results, as it imparts an unpleasant taste to the eggs. The author proposed to exclude oxygen by coating the shell with a solution of some kind which closes the pores of the shell airtight. Practical trial of this method gave very encouraging results. A large number of eggs were inoculated with bacteria and then some of the eggs were coated. Those not coated spoiled within a week, but the coated eggs kept perfectly for two months without change in color, flavor, or odor. The exact nature of the coating was not given.

In bacteriological tests made by Rettger³⁹ of more than 10,000 eggs of different ages, under various degrees of incubation, yolks from fresh eggs showed a positive test for bacteria other than *Salmonella pullorum* of 9.15 per cent. The yolks of artificially incubated eggs showed 2.75 per cent positive tests during the first week of incubation, 1.3 per cent the second, and 3.6 per cent the third week. The small percentage of positive results for eggs which had been incubated from one to three weeks was considered a noteworthy fact. A more exact method was employed in testing the yolks of fresh eggs, and in this case the test was reduced to 3.86 per cent. It was believed that these results were, in all probability, considerably above the actual figures, could accidental invasion of bacteria in the tests be entirely prevented. Experiments with eggs incubated one to two weeks indicated that fertilized eggs did not become more subject to bacterial invasion of the yolk than the infertile eggs. Examination of the whites of 582 eggs indicated that 1.2 per cent contained bacteria, although many of the tests were made during the summer months. No *Salmonella pullorum*, the organism of white diarrhea, was detected in the white, although it was recovered from the yolk. Undoubtedly, there was some contamination in these tests, and it was believed safe to say that the whites of fresh normal eggs are, as a rule, sterile. Fermentation tests made of the whites of 105 eggs for *Escherichia coli* were negative. In noting the kinds of organisms found in the yolks of fresh and incubated eggs, it was observed that a large percentage in both cases were staphylococci, usually *Staphylococcus albus* or *Staphylococcus aureus*, indicating that there was considerable contamination in the examination. Also the occurrence of a large number of members of the subtilis group would suggest the same thing.

Rettger reviewed the results obtained by earlier investigators which are not in harmony with those which he obtained. He suggested that the methods employed in making previous tests may have been at fault and it was highly improbable that normal fresh eggs contain bacteria and molds in such large proportions as various investigators have indicated. It was stated that the developing ova in the ovary of a laying hen were, as a rule, sterile unless the ovary was infected with the organism of bacil-

Nonacid Foods: *Bacillus stearothermophilus* is a member of this group of bacteria causing "flat-sour" spoilage of vegetables. These bacteria are facultative with respect to oxygen, which makes it possible for them to grow under widely divergent conditions. Spores with quite high heat resistance are formed.

Acid Foods: There is a newer type of spoilage that affects products which are relatively acid in character, particularly tomatoes and some tomato products. *Bacillus thermoacidurans* is the typical species of spoilage organism. It is an aerobic, acid-tolerant bacterium, spores of which are not as heat resistant as are the spores of other spoilage bacteria. It is discussed on page 667.

2. **Thermophilic Anaerobic Bacteria.** These bacteria grow only in the absence of air. They form very heat-resistant spores. Growth is accompanied with both gas and acid production so that the container swells. *Clostridium thermosaccharolyticum* is the name given to these organisms.

3. **"Sulfide Spoilage" Thermophilic Bacteria.** The name "sulfur stinker" was given to these bacteria when they were first isolated. *Clostridium nigrificans* is the type species.¹³⁸ It produces large amounts of hydrogen sulfide which turns the contents of cans of food in which it has developed, quite dark. Economically this group is not important for it causes few outbreaks. When it does strike, however, its effects are spectacular and costly.

The above groups are composed of thermophilic bacteria. Several other groups of bacteria exist which are not thermophilic but which cause much loss.

4. **Putrefactive, Anaerobic Bacteria.** These are the truly putrefactive anaerobic bacteria, growth of which is indicated by gas formation and digestion. The anaerobic, sporeforming species are in this group.

Yeasts as Spoilage Organisms of Canned Foods. Yeasts have not been significant organisms in spoilage of canned foods. They may cause spoilage in some fruits in sirup which have not been processed at sufficiently high temperatures or for a sufficiently long time. At best the spoilage caused by yeasts is relatively insignificant. Townsend and Powers¹²⁴ found the most-resistant spoilage organism in orange juice was a heat-resistant yeast which survived up to one minute at 76.7°C. (170°F.).

Molds as Spoilage Organisms of Canned Foods. Molds have not caused much trouble for the canner. On one or two occasions they have been found to have survived the process and caused spoilage. The best-known and most-typical cases are those reported by Olliver and Smith¹²⁵ and Williams, Cameron, and Williams.¹²⁶ The former isolated *Byssoschlamys fulva* from processed fruits in England. Its ascospores resisted 86 to 88°C. (186.8 to 190.4°F.) for 30 minutes. Williams, Cameron, and Williams¹²⁶ isolated a mold from canned blueberries. Sartory and Meyer¹²⁷ also reported a mold from canned foods. *Byssoschlamys fulva* has been studied

especially by investigators in England. Hirst and McMaster¹²⁸ reported that spoilage of canned fruits by this mold took the form of a complete breakdown in texture so that on slight shaking it disintegrated completely. In some cases the mold could be detected by the naked eye, while in others the microscope was required to detect it. The can may be swelled, but in most cases the cans examined had a good vacuum. The spores of this fungus were found on a few samples of fruit on which it was carried into the factory. Heat-resistance studies of the spores in various canned fruits indicated appreciable resistance. Hirst and McMaster used fruits as the substratum, which might account for shorter survival periods than were reported by Olliver. Further experiments by Hull¹²⁹ revealed that longer survival times were observed when the spores were heated in sucrose. Actual survival times depended on the conditions under which the experiments were carried out. A temperature of 87.8 to 93.3°C. (190 to 200°F.) was necessary at the center of the can under experimental inoculation; natural infection was destroyed at an internal temperature of 82.2°C. (180°F.). Hull believed that in order to destroy resistant spores 90.5°C. (195°F.) at the center of the can would be necessary. Gillespy's¹³⁰ results seemed to confirm this.

Some of the conditions which influence heat resistance of ascospores of *Byssochlamys fulva* in fruits are concentration of sucrose and presence of a little sulfur dioxide. Gillespy observed what has been observed with bacteria and yeasts that the more sugar present the harder it is to destroy the ascospores. Small concentrations of sulfur dioxide at pH values below 3.7 increased the lethal effects of heat on these ascospores.

Classification of Types of Spoilage of Canned Foods on the Basis of Acidity. Canned foods are divided into two, and perhaps three, classes as regards processing. Bigelow and Cameron¹³¹ and Cameron and Esty¹³² have referred to these as *nonacid*, *semiacid*, and *acid* foods. Cameron and Esty suggested the following classification which they termed, "Acidity Classification of Spoilage Types":

Group 1. Low acid, pH 5 and higher.

Group 2. Medium acid, pH 5 to 4.5.

Group 3. Acid, pH 4.5 to 3.7.

Group 4. High acid, pH 3.7 and below.

Group 1. Low Acid, pH 5 and Higher. Cameron and Esty placed meat and marine products, milk and certain of the common vegetables in this group. The common thermophilic bacteria may spoil all of these foods although they do not ordinarily attack meat and marine products. Mesophilic putrefactive anaerobes are important agents of spoilage in this group.

Since Barlow¹¹⁵ revealed that thermophilic bacteria were important in certain types of canned-food spoilage, numerous others have reported the

isolation of such organisms. Donk¹³³ isolated a species to which he gave the name *Bacillus stearothermophilus* from corn. Shaw¹³⁴ isolated 23 strains of thermophilic bacteria from fruits and vegetables. She proposed the name *Bacillus pepo* for one strain from pumpkin.

Stevenson¹³⁵ gave two explanations for "black beets"; one was that the discoloration was enzymic in nature and the other was that it was a bacterial spoilage. Cameron, Esty, and Williams¹³⁶ had an opportunity to study an outbreak of spoilage of this nature in sliced beets. The spoilage was said to be due to understerilization but in order for the bacteria to produce their characteristic effect, it is necessary that an abnormally large amount of iron be present in the beet liquor. The causal organism was described and named *Bacillus betanigrificans*. The iron was said to accelerate the growth of the organism. The organism did not grow at 55°C. (131°F.).

Malodorous or "sulfide spoilage" of peas and corn is not a significant one as far as the number of outbreaks is concerned; it is serious, however, for the packer when it does occur. Cameron¹³⁷ stated that the research laboratory of the National Cannery Association had a record of only four outbreaks in corn and one in peas. Hydrogen sulfide gas is produced, to which the bad odor is due. The can remains flat, owing to the fact that the gas formed dissolves in the liquor. The sulfur compounds react with the iron which gives the liquor a black color. Cameron investigated the source of these thermophilic bacteria in canned peas by investigating the water, salt, sugar, and tanks in which the brines were made. He discovered the organism which Werkman and Weaver¹³⁸ named *Clostridium nigrificans*. This organism caused a very pronounced spoilage in peas, evidenced by the blackening of the liquors. Cameron's work seemed to indicate that the canned peas were seeded with the spores of this organism by the brine which was prepared in wooden tanks. Shavings from the staves of the wooden hot-water tank were found to be badly infected with the spores of the hydrogen sulfide-producing, thermophilic organism. Cameron, Williams, and Thompson¹²³ have made a longer report on this spoilage.

Group 2. Medium Acid, pH 5 to 4.5. In this group, which Cameron and Esty said was really a subdivision of Group 1, are principally meat and vegetable mixtures and "specialties," such as spaghetti, soups, and sauces. Bacteria involved in this group are essentially those mentioned above for Group 1; in some of these foods putrefactive anaerobes may develop, resulting in nongaseous changes in the food.

Group 3. Acid, pH 4.5 to 3.7. In this group are tomatoes, pears, figs, pineapples, and nectarines. These products are subject to spoilage by nonsporeforming, aciduric bacteria and sporeforming anaerobes allied to *Clostridium pasteurianum*. Some of the organisms which fall in this group

have been studied by Townsend.¹³⁹ They were isolated from swelled cans of tomatoes, pears, pineapple, pimientos, and chilies. Some of the strains were sufficiently acid-tolerant to grow in almost any canned food if the medium was otherwise suitable. Spoilage caused by nonsporeforming, coccoid bacilli indicated to Townsend understerilization or defective can seams. Cooks of certain acid foods which give a temperature of only 98.8°C. (210°F.) at the center of the can are not high enough for sterilization if any considerable number of spores are present.

The strains which Townsend used, isolated from the foods mentioned above, were arranged in four groups as follows:

Group I. Facultative anaerobes. Small, gram-positive, coccoid bacilli, producing gas in certain food juices but not in artificial media. They do not produce spores and are nonmotile. They are saccharolytic and some strains are remarkably tolerant to acids. The resistance to heat is very low.

Group II. Facultative anaerobes. Small, gram-positive, nonsporeforming, motile, coccoid bacilli. They are very saccharolytic and produce a great deal of gas. The heat resistance is very low.

Group III. The flat-sour organisms. Facultative anaerobes. Short, gram-positive, motile rods, forming central spores. They are very saccharolytic but do not produce gas. A resistance to heat of 16 minutes at 100°C. (212°F.) using 800 spores, has been obtained.

Group IV. Obligate anaerobes. Form clostridia at sporulation. Small to long, gram-positive rods with oval, subterminal spores. They are very saccharolytic, with the production of much gas. The resistance to heat of one strain is 13 minutes at 100°C. (212°F.), using 1,000 spores.

All of the organisms studied were mesophiles, since optimum temperature for growth was 37°C. (98.6°F.). The characteristics of the organisms were given in considerable detail by Townsend, although in several instances only general statements could be made. This grouping was quite similar to one published previously by Esty.¹⁴⁰

Heat-resistance studies were carried out by Townsend¹⁴¹ with cultures from each group using generally accepted methods. Spore crops were secured by growing the organism in liver broth at 30°C. (86°F.) for 16 to 20 days. After concentration by centrifuging, the spores were stored at about 5°C. (41°F.) in a portion of the medium in which they had been grown.

"Heat resistance was determined by the method of Bigelow and Esty¹⁴² using two-ml. amounts of suspension in six-mm., inside-diameter Pyrex tubes, sealed after filling. Three tubes of each suspension were removed from the water bath at each time interval and immediately cooled. The thermal death-time tubes were then subcultured into tubes of liver broth from which the air had been exhausted by boiling, stratified with vaseline to provide anaerobic conditions, and incubated at 30°C. Gas production was the criterion for growth. A one-minute lag was allowed from the time the tubes were put in the water bath until the start of the heating test was recorded. Three temperatures were used, 90, 95, and 100°C. (194, 203, and 212°F.). Foods tested were tomatoes, pears, and apricots of different pH values."

The spore suspensions were standardized by dilution in liver-broth tubes after heating in boiling water for two minutes and cooling. Obser-

vations were made at 90, 95, and 100°C. (194, 203, and 212°F.) in phosphate buffer solution at pH 7.0 and in juices of tomato, canned pears, and canned apricot. Townsend¹⁴¹ published results in a large table.

Acid-tolerant, butyric acid-producing, sporeforming anaerobes which had caused a number of outbreaks of spoilage in canned fruits and tomatoes in widely separated districts were isolated and studied by Townsend. One strain was thoroughly studied for its heat-resistant characteristics. Townsend reported its characteristics and especially its heat resistance in some 10 different acid food products.

According to Townsend, these bacteria are widely distributed in the soil. Owing to their ability to endure higher sugar concentrations and acid, they have become of importance in the canning industry. Control is difficult, for their presence in canned food does not result from factory contamination but rather from presence in raw materials as brought into the factory. About the only alternative, according to Townsend, is acidification since marked reductions in pH greatly affect the resistance of the spores to heat. Townsend's results indicated that to destroy spores of these organisms in tomato juice at 100°C. twice as long at pH 4.5 as at pH 4.1 is required and nearly five times as long as at pH 3.8.

These organisms were also isolated from bursting swelled cans of pineapple by Spiegelberg,¹⁴³ who recognized two culture types. In general they were similar to *Clostridium pasteurianum* as described by Winogradsky¹⁴⁴ and others. Spiegelberg also found pH to be important in controlling these bacteria. He concluded that a final pH of 4.4 or below and processing to a given temperature in the can of 87.8°C. (190°F.) would prevent spoilage in canned pineapple by *Clostridium pasteurianum*, *Lactobacillus plantarum*, and *Leuconostoc mesenteroides*. The percentage of butyric swells in this work was proportional to the number of spores added to the cans before processing.

A special group of organisms studied by Mickle and Breed,¹⁴⁵ Pederson,¹⁴⁶ and Pederson and Breed¹⁴⁷ has been especially troublesome in tomato products. Gaseous spoilage of these products was traced to an organism to which the name *Lactobacillus lycopersici* was given by Mickle. Two hundred and sixty-six strains of tomato-products spoilage organisms were studied by Pederson. All were members of the genus *Lactobacillus* and were unable to withstand the temperatures used in bottling catsup or in canning other products.

Investigation of serious outbreaks of spoilage in canned tomatoes resulted in isolation of a thermophilic, sporeforming anaerobe by Woerz and Lenane.¹⁵⁰ Spoilage reached 10 per cent in some daily packs. Good growth with gas formation occurred in less than 24 hours at 51.6°C. (125°F.). The

anaerobe formed spores none too readily and exhibited considerable resistance to heat. It withstood boiling for at least 15 minutes in tomato juice having a pH of 4.2. It was definitely thermophilic, growing only at a temperature of 43.3°C. (110°F.) or higher. Discovery of such an organism as this as the cause of gaseous spoilage of tomatoes indicates that accepted methods of processing might not always be adequate. Application of sufficient heat to destroy spores of this organism might result in an inedible product. Consequently, Woerz and Lenane believed that the answer to this problem is more than increasing processing time.

The foods in this group have been generally considered to be free from any botulism hazard. Occasionally, however, some canned food in the group has caused this intoxication. Slocum, Welch, and Hunter¹⁵¹ listed nine outbreaks of botulism from eating acid food products. This tabulation was included in a report of an outbreak caused by home-canned tomatoes. The pH of a quart jar which seemed to be normal in appearance and odor was 4, well within the critical value of 4.5 which is considered to separate potentially dangerous foods from those which are not. It is well to point out, however, that this value was secured with *Clostridium botulinum* in pure culture in acid foods. All but one of the above nine outbreaks were caused by home-canned foods which were not well sterilized. In several it was shown that other bacteria were present which may have destroyed some of the acid and permitted *Clostridium botulinum* to grow. Slocum *et al.* found in addition to *Clostridium botulinum* a sporeforming bacillus and a coccus.

Group 4. High Acid, pH 3.7 and Below. This group, according to Cameron and Esty,¹³² includes foods which are relatively free from spoilage caused by sporeforming bacteria, such as kraut, pickles, berries, grapefruit, citrus fruit juices, and rhubarb.

METHODS FOR EXAMINATION OF CANNED FOODS

Bacteriologists examining canned foods should know as much as possible about the conditions under which the food is canned. They should also give attention to the can from which the food was taken. The presence of perforations would greatly influence the conclusions which are drawn from the bacteriological data. Below are given methods for both bacteriological and physical examination of the containers.

TYPES OF SPOILAGE

A number of characteristic names have been slowly developed for indicating abnormal conditions of canned foods. Few of them may be regarded as absolute terms; however, they indicate in a general way the type and, in some cases, the degree of abnormality. They have become convenient terms and have wide usage.

Flat Sours. A flat sour is a flat can (one with concave ends) which shows the presence of greater acidity than the normal. There is no characteristic production of gas, the decomposition having stopped in the acid stage. The absence of gas leaves the ends of the cans flat and not bulged. These two characteristics, flat ends and an acid reaction, indicate the origin of the term. Since no gas is characteristically formed, this type of spoilage cannot be readily detected from the exterior. The causes of flat sours

151. Slocum, Welch, and Hunter. 1941. Food Research 6, 179-187.

are probably not complicated. They are due almost entirely to understerilization or leaky cans. Thermophilic bacteria are especially significant in the production of flat sours.

Swells. These are cans with bulged ends. They result from a number of causes one of which is bacterial growth. Gas formed in cans forces the ends of the cans out and gives them a bulged, distorted appearance. The several causes of swells may be tabulated:

1. Biological swells—resulting from the development of gas-forming bacteria.
2. Chemical swells—resulting from the action of the contents of the can on the container with formation of hydrogen.
3. A third type due to chemical decomposition of the material in the can—"Schaumgärung."
4. A fourth type may be due to overfilling at low temperatures..
5. A fifth type may be due to altitude where the cans would be under reduced pressure.

Serger¹⁵² classified the causes of swells as follows:

1. Gas formation from bacterial growth—true of biological swells.
2. Gas formation from chemical processes—chemical swells.
3. Absorbed gas—pseudo swells.
4. Pressure generation by freezing—cold swells.
5. Pressure formation by cellular dilations.

He divided the swells under the first subdivision into two parts, (a) those which are infected after sterilization and (b) those which are understerilized. Serger has shown that the pressure may reach 3.5 atmospheres.

The conditions favoring the formation of hydrogen swells and perforations were stated to be as follows by Morris and Bryan:¹⁵³

1. Low acidity (syrup in the neighborhood of pH 4).
2. Lacquer on the inside of the can.
3. The presence of substances, such as sulfides, which accelerate corrosion with products of high acidity.
4. Storage of the canned foods at high temperatures, and inefficient cooling of the cans after processing.
5. The presence of solids and other substances which absorb tin salts and so encourage de-tinning and consequent exposure of the iron.
6. Inefficient exhausting which leaves oxygen in the can after sealing and encourages de-tinning.
7. Insufficient head space in the can so that any hydrogen which may be produced will cause the can to swell rapidly.

The microbiology of biological swells is discussed at various places in this book. Swells which occur in nonacid or vegetable foods are due mostly to growth of bacteria, while those in acid foods are due to chemical reactions between the metal and the acids. Esty¹⁵⁴ reported that of 338 swelled cans of fruit tested, 231 were due to hydrogen formation and 107 to biological fermentation; of a total of 600 cans of swelled tomatoes all were found to be unsterile.

Lueck¹⁵⁵ called the attention of canners to the possibility of "frothy fermentation" or "Schaumgärung." The name was applied to a type of spoilage erroneously attributed to understerilization. This type of spoilage, as the name indicates, is characterized by the appearance of considerable amounts of carbon dioxide which give to the product a frothy or foamy

appearance. It occurs mostly in sirup products, such as table sirups, malt extract, prunes in sirup, etc., and may cause the bacteriologist some concern. About all of the evidences of bacterial spoilage will be present, yet no viable microorganisms can be isolated.

Sturgess, Drake, and Parsons'¹⁵⁶ **Method for Determining the Swelling Rate of Canned Foods.** The inadequacies of the older unscientific methods for determining the swelling rate of canned foods caused Sturgess, Drake, and Parsons to apply the familiar principle of determining density by weighing under water. It is obvious that the change in density of a given sealed container will be a measure of the increase or decrease in volume of the container. This can occur in canned foods only because of evolution or absorption of gases. A large rough balance of an accuracy of .1 gram is arranged so that a fine piano wire can be attached to the bottom of one pan and passed through holes of suitable size drilled through the base of the balance and table top. The wire terminates in a small hook which engages a small copper loop previously soldered to the cans to be tested. The wire, immersed in water to the operating level, is carefully weighed and a tare made and added permanently to the weights in the other pan. The container is of a suitable size to accommodate the type of can to be tested. It is equipped with an electric heating element of 100-200 watts, a thermometer, and an air stirrer. The authors believed that thermostatic control of the temperatures was unnecessary. Manual control to within .5°C. was sufficient.

When the bath has been adjusted to the temperature at which incubation has been carried out, the can is quickly immersed in the water, care being taken to avoid entrapment of air under and along the flanges of the can. The weight is determined by adding suitable weights. If the wire is sufficiently fine, no special care need be taken to have the water level exactly constant since the error involved is only the weight of a section of wire corresponding to the difference in level.

For all practical purposes it is sufficient to assume that the density of water is unity at the operating temperatures. To determine swell, it is necessary only to measure the weight of a given can under water at various intervals, the decrements in weight in grams being equivalent to the swell in milliliters. If it is desired to calculate the percentage swell of a given can, it is necessary to know the approximate initial volume of the can. This, of course, involves simply weighing the can in air.

Following the simple relations involved:

W_{air} = weight of can in grams in air

W_{water} = initial weight of can in grams in water

V = initial volume of can

D = average density

$$V = \frac{W_{air} - W_{water}}{D}$$

$$D = \frac{W_{air}}{W_{air} - W_{water}}$$

If W = the decrement in weight in water, the percentages swell S is

$$S_2 = \frac{W \times 100}{V}$$

Sturgess, Drake, and Parsons found that variations of two ml. in volume on cans of 3,000 to 4,000 ml. could be detected. The variation in weight may be shown by plotting the "percentage swell" against the time in days.

Composition of Gases in Canned Foods. Baker¹⁵⁷ found no oxygen in gas from sound cans of food. He attributed this to oxidation of tin and

156. Sturgess, Drake, and Parsons, *Food Indus.* 3, 105.

157. Baker, 1912. *Eighth Internatl. Cong. Appl. Chem.* 18, 45-49.

iron salts, and combination was nascent hydrogen. The following analyses were reported for hydrogen swells:

	Red raspberries 18 mo. old	Strawberries 18 mo. old
Carbon dioxide.....	8.40	12.60
Oxygen.....	.00	.00
Hydrogen.....	65.50	72.40
Nitrogen.....	26.10	15.00

These results agree well with those of Tonney and Gooken¹⁵⁸ and Serger.¹⁵²

Breathers. A breather is a can which is probably bacteriologically tight but not “airtight.” Consequently air passes back and forth into the can through the gasket depending on the temperature of storage. Breathers are cans with low vacuum. From the standpoint of spoilage and food decomposition, breathers may not be of much significance since the gasket may act as a filter keeping microorganisms out of the can.

Springers. A springer is a can which is slightly bulged at one or both ends. Springers may be potential bacterial or chemical swells. Springers may also result from improper exhausting, packing cold, etc. They become slightly bulged when stored under warm conditions owing to expansion of the gases in the can. Loss of vacuum on account of imperfect closure may also cause springers.

The problem of springers in canned meats has been extensively reviewed by Hallman.¹⁵⁹ While only one factor may be involved in causing them, several may be involved. Generally speaking, springers may be reduced in incidence by employing methods of canning which insure good vacuum in the can. This requires proper exhausting and filling, leaving a little head space, and not overfilling.

Flippers. A flipper is a can the ends of which may be driven out by striking against a hard object. Flippers are one step removed from springers. They are generally due to insufficient exhaust or loss of vacuum. The lines demarking springers, flippers, and swells are not definite. Under different temperature conditions a flipper may be made to become a springer and a springer, a swell. This, of course, is without reference to the condition of the contents. These terms cannot be given strict scientific definition but the trade seems to have accepted the term “swell” for spoiled cans and the terms “flipper” and “springer” for cans which are not necessarily spoiled.

Buckled Can. A buckled can is one which has been handled in a rough manner which has caused the end panel to be permanently bent out of shape. This usually occurs near the seam. Buckled cans may also be caused by insufficient exhaust, or overfilling. With large-diameter cans, such as the No. 10s’, buckles can scarcely be avoided with heavy process unless the cans are cooled under pressure.

Understerilization. This term does not need definition. If the container is tight so that no bacteria may enter, the presence of viable spores would be due to understerilization. Bacteriologists are often asked why processes which have apparently given satisfactory results for years, suddenly become inadequate with great spoilage resulting. Process times and temperatures have been adopted for what may be termed average conditions, i.e., average bacterial load or contamination, average resistance of these bacteria, etc. If, for instance, the number of spoilage bacteria to be killed is excessive, all of them will not be killed and understerilization will result. The sudden appearance of heat-resistant spoilage bacteria has upset many processes. Before the presence of viable bacteria in cans of food may be attributed to underprocessing, the condition of the container must be ascertained by an experienced technologist.

159. Hallman. 1941. Food Indus. 13, 67-68.

Botulism and Canned Foods. Commercially canned foods have been remarkably free from botulism since 1924. Since then only one outbreak has been reportedly due to a commercially preserved product, and that was a specialty product, mushroom sauce. This situation results from a carefully planned attack on the botulism problem by canners. It is reviewed in *Food-Borne Infections and Intoxications* by the author of this book.

Origin of Spoilage Bacteria in Canned Foods. Spoilage bacteria have been found to come from various sources. The relative importance of each depends to a large extent on the food.

Spoilage Organisms in Raw Foods. Such organisms can rarely be eliminated. They may be reduced somewhat in numbers by such operations as peeling and washing. Cameron¹⁶⁰ did not consider soil contamination of raw foods as important unless there was direct mechanical transfer. Similar conclusions had been reached 10 years earlier by Cameron, Williams, and Thompson.¹²³ These are probably general conclusions for all foods and surveys which they made. Townsend¹⁶¹ showed that certain areas are heavily seeded with thermophilic bacteria which cause spoilage in canned asparagus. Soil was taken from certain badly infected fields and inoculated into cans of asparagus. Spoilage varied from 100 per cent for the top 12 inches to none at 36 to 42 inches in depth.

Various species of bacteria were isolated by Highlands¹⁶² from freshly cut, whole-grain corn. Those which were reported were of no significance to the canner. No thermophilic bacteria were found.

Spoilage Organisms on Canning-Plant Equipment. Bacteriologically unclean canning-factory equipment may contribute significant numbers of spoilage bacteria to food to be canned. This knowledge has become the basis for efforts in factory sanitation. This involves more than mere dressing up of the factory. In addition, washing with steam and hot water and scraping are resorted to. Cameron, Williams, and Thompson's¹²³ bacteriological field studies in canning revealed that when undue spoilage occurs from understerilization, much of it results from accumulation of spores of spoilage bacteria in various units of factory equipment. In canning of peas and corn, such development is possible where heat is used. Blanching and filling equipment and wooden brine tanks were potential sources of contamination. Cameron¹⁶³ made the same observations for pumpkin.

In 1926 and 1927, Cameron and his colleagues found that the use of wooden brine tanks, on account of their construction, might contribute significant numbers of microorganisms to corn. When metal-lined tanks were used, fewer bacteria were contributed to the brine. Cameron⁴⁶ reported more results to confirm this opinion secured from experimental packs during the season of 1929 before the annual meeting of the National Canners Association in Chicago. Marked resistance to heat on the part of anaerobic thermophilic bacteria was observed by Paine.¹⁶⁴

164. Paine. 1931. *Centbl. Bakt.*, Pt. 2, 85, 122-129.

Another important source of spoilage organisms may be the canning factory itself if it is not properly cleaned. Outbreaks of spoilage have been traced to development of spoilage bacteria at some place in the factory. The foodstuff was, in this way, contaminated by large numbers of those bacteria which the canner strives to avoid. Thorough cleaning-up stopped these outbreaks. Cameron's work showing that the wooden brine tank produced contamination has just been mentioned. That blanchers, silkers, cutters, etc., may also infect the foodstuff has also been well proven. When these are made bacteriologically clean, the contribution of spoilage bacteria is greatly reduced. Every effort must be made to remove every particle of food when the day's run is ended, else bacteria will have an opportunity to develop. This is best accomplished with a steam hose and brushes.

Whether a canning factory is free from excessive numbers of undesirable bacteria is best proved by bacteriological tests. These should be made on the salt, sugar as outlined in Chapter 19, soil, and the various pieces of machinery in the canning factory.

Spoilage Organisms in Ingredients Added to Canned Foods. Canned-food technologists, as a part of the entire program of restricting contamination of canned foods, had to give attention to certain ingredients, such as sugar and starch. In some instances much of the good which had resulted from prompter handling of raw foods and better factory sanitation had been negated by spoilage microorganisms in the ingredients. These were frequently prepared under ideal conditions for fostering development of these microorganisms.

The first ingredient to be actively investigated was sugar. Since this work is discussed in Chapter 19 of this book, it will not be treated here. In addition to sugar other ingredients, such as dry milk, sirups, malt extract, various sweetening agents, and flour, may harbor spoilage bacteria.

This problem for the canner has been partially solved by preparation of materials by the manufacturer which are relatively free from the undesirable bacteria. As mentioned elsewhere in this book, standards have been established for sugar and standard methods prepared for use with them.

That spoilage bacteria in ingredients just mentioned may be significant to the canner has now been definitely proven. Cameron, Williams, and Thompson, in their plant surveys, found sugar in use which contained 25 and 40 flat-sour-producing bacteria per gram. Corn brine containing a maximum amount of 225 pounds of sugar in 200 gallons of water would yield cans of corn containing 450 and 750 spores per can, respectively. The actual significance of thermophilic canned food spoilage bacteria in sugar has been shown in Chapter 19. Results of investigations with sugars having different numbers of thermophilic bacteria have definitely related canned food spoilage to contaminated sugar.

Spoilage Organisms on Machinery in the Factory. Bacteriologically clean equipment in the canning factory is necessary to keep the load on the process as light as possible. The importance of this was shown by Cameron, Williams, and Thompson.¹²³ They observed thermophilic contamination of peas and corn to increase by plant shutdown. It was greatest in the

morning after overnight shutdown. When the plant operated steadily, thermophilic contamination steadily decreased.

An important source of spoilage organisms in some plants were the wooden brine tanks which became soft and porous. Bacteria became imbedded in the wood and were contributed to the brine. While not all wooden brine tanks are in this category, they are potentially hazardous and should be examined bacteriologically if there is reason to suspect them. Metal or metal-lined tanks are best.

Another source of spoilage bacteria may be the fillers and blanchers. Contamination in the latter, according to Cameron, Williams, and Thompson,¹²³ is built up during a shutdown. Under steady operation such contamination was washed out and became less and less. They advised, therefore, running the blancher with a full flow of water for 30 minutes or so before actual canning operations begin.

Investigation of Outbreaks of Spoilage in Canned Foods. These must be complete and adequate in every respect. They should be carried out by, or under the direction of, experienced technologists, for the proper interpretation of results requires considerable knowledge of canning procedure and microorganisms which have been proven to cause spoilage. The following are basic. The whole subject was completely presented by Cameron, Williams, and Thompson.¹²³

Selection of Spoiled Cans. In many outbreaks of spoilage this is not difficult. If the cans are "hard swells," such cans, of course, are the ones to examine. On the other hand, if the spoilage is due to development of flat-sour producing bacteria, the problem is not so easy. In this case the spoiled cans may give no visual evidence that they are unsound and the analyst must use his ingenuity.

In the latter case the first thing he may do is to incubate the cans in order to develop the organism which is causing the trouble. Townsend¹⁶⁵ recommended 36.7°C. (98°F.) for 14 days and 57.2°C. (135°F.) for 12 days for low-acid products and 29.4°C. (85°F.) for fruits. While these recommendations were for determining sterility, they are satisfactory for any other purpose.

Gross Observations on the Cans. In addition to those recommended by Esty and Stevenson¹⁶⁶ and quoted on page 1000, Townsend recommended determination of vacuum, net and drained weights, head space, and pH because some of this information indicates how the product was packed. Vacuum and pH determinations will indicate microbial growth and formation of acids by flat-sour-producing bacteria. Loss of vacuum may be due to gas formation by microorganisms. If the contents of such cans are to be used for bacteriological examination, the above observation must be made very carefully so as not to contaminate the samples. An important part of this so-called physical examination is observation of all code marks on the can and a record of labels.

165. Townsend. 1939. *Western Canner and Packer*, June, July, and August, 1939.

166. Esty and Stevenson. 1925. *J. Infect. Dis.* 36, 486-500.

After all the above, the can itself must be carefully "taken down" by an experienced can technologist to determine whether the seams were properly made to prevent ingress of microorganisms.

Microscope and Bacteriological Examination of Contents of Can. Such observations must be made on samples which have been collected very carefully and not subjected to possibilities of contamination. Only experienced canned-food bacteriologists appreciate the care which must be taken.

Direct microscope examination may be made of a film of the food spread on a glass slide and stained. Such observations will indicate the general type of microorganism present.

Bacteriological examination must be made with the best technic and culture media known to support development of spoilage bacteria. These special directions are given a few pages farther on in this chapter.

Plant Survey—Collection of Samples in the Canning Factory. This work is necessary to determine whether any practice in the factory is seeding the food with undue numbers of spoilage bacteria. Samples must, therefore, be taken of the raw, unwashed food, at the washer, blancher, brine tank, and from cans about to be closed for the retort. When wooden equipment is used, small pieces should be examined to determine whether the wood is seeded with spores. Samples of water and brine should also be examined. Townsend pointed out the value of data collected during the packing period. Undue amounts of spoilage in the product packed after shutdowns would indicate development of spoilage bacteria on bacteriologically unclean machine surfaces and lines. Owing to dilution such contamination would decrease during the packing period.

The cooling water should not be overlooked for this may be heavily contaminated. The cans enter the cooling tanks hot. During cooling, bacteria in the cooling water might be drawn into the can through microscopic leaks. Cooling water with few bacteria would be of little importance but water heavily seeded might contribute many bacteria to the can. Under some conditions cooling water should be chlorinated and observations regularly made to insure maintenance of sufficient residual chlorine.

Interpretation of Results. After having collected all possible data, the problem is to decide on the real cause and to institute procedures for correcting the difficulty.

Incubation Tests on Canned Foods. The subject of incubation was discussed above in connection with the laboratory examination of canned foods. Incubation tests are also of great value in another connection, as discussed by Thompson and Cameron.¹⁶⁷ They are used in the canning factory to determine "commercial sterility" during the days that the factory is in operation. Thompson and Cameron stated that contamination was heavier during the first few minutes after the factory is in operation, and since this contamination will decrease as the factory is operated, they advised taking cans from the first crate from each line in the morning and again in the afternoon. This would give cans with the greatest and prob-

167. Thompson and Cameron. 1928. *The Canner*, June 9, 1928.

ably the fewest bacteria and would therefore represent the best and the worst cans for the day. It was advised that two cases be taken from each line at each sampling period for incubation. One case should be incubated at 37°C.(98.6°F.) and the other at 55°C.(131°F.). This type of incubation gives the canner evidence of danger within a few days after operation of the factory has started. The cans should be carefully marked in such a manner that a complete record may be kept.

Incubation at 55°C.(131°F.). Incubation at this temperature should show the presence of thermophilic bacteria of both the "flat-sour" and "swell-forming" groups as well as growth of the obligate and facultative thermophiles. The true or obligate thermophiles will grow only at 55°C. The presence of the flat-sour thermophiles can only be determined after the cans have been opened by testing the contents with an indicator such as brom-cresol-purple. The changes in color from purple to yellow show the presence of acid and should be taken as a danger signal.

Another serious spoilage which can be determined only after the cans have been opened is "sulfide spoilage." The food, usually corn and peas, shows a dark discoloration. This type of spoilage should develop in three or four days at 55°C. and in about 10 days at 37°C.(98.6°F.). When this type of spoilage appears, there may be an immediate increase in the process since this is one of the most serious types of spoilage with which to deal, or measures may be taken to decrease contamination of the food product. The appearance of swells after incubation at 55°C. should cause the canner to provide better cooling.

Incubation at 37°C.(98.6°F.). Incubation at this temperature should show the presence of facultative thermophilic and mesophilic bacteria. These organisms will grow at the usual temperatures of storage, and foods containing them are quite liable to spoil.

Swells which appear on incubation may be due to thermophilic, gas-forming bacteria or to non-thermophilic, anaerobic sporeformers.

Criteria of Spoilage. The analyst must use every possible observation to reach the proper diagnosis of spoilage. In most cases there is some reason prompting the request for examination of the cans. They may have been regarded as the causal agent in illness or have been prepared from unsound raw materials. The examination may be prompted by the desire of a food official to determine the character of the product. Finally, the packer may desire to know the organisms involved in an undue amount of spoilage.

The most evident criterion of spoilage is the absence of flat ends. If the ends are bulged, it means that the can has been overfilled, improperly exhausted, understerilized, insufficiently cooled, or subjected to some other defect in the process of manufacture. The bacteriologist must determine whether the can has received sufficient heat treatment to destroy all forms of life in its contents. The absence of bacteria does not necessarily indicate that they were not present at an earlier time. They may have been destroyed by their own products of catabolism. Bacteriological results, of

course, are most valuable in determining whether the contents of the can are sterile.

Another criterion of spoilage is the evidence that is available after the can is open. In some cases, no bacteriological tests are necessary to prove this. They may be valuable, however, in determining the characters of the bacteria causing the spoilage. However, the detection of spoilage by judging the appearance of the canned product is not always a safe method. The analyst must be familiar with the normal product and thus be able to use it as the standard with which to compare the suspected food.

Sampling and Data Accompanying the Sample. This is very important and a procedure to which the packer or person desiring the examination often gives too little attention. The analyst is better fitted if he has knowledge with regard to the various steps used in canning the food under examination. These should include, of course, the times and temperatures of the process and other steps in the preparation of the food.

The number of cans which should be used by the analyst is determined only by the purpose of the examination. It is obvious that the examination of a single can would yield results which would not be conclusive. It is better to examine even five or six or more, when they are available, especially if the results are to be used in the control of the packing process. Along with the cans which are under suspicion should be sent a few cans which are thought to be normal. The analyst may wish to examine the latter, or even to inoculate them with microorganisms isolated from the spoiled cans. Bigelow, of the Research Laboratories of the National Canners Association, suggested that at least a case of the food to be examined be sent to the laboratory. The best plan is for the analyst to go to the canning factory and collect the samples himself. At least a case of the smaller size cans should be available at the laboratory. Under certain conditions cans should be taken from the lines during the day in order to get a distribution which would include the product packed under different conditions. Esty and Stevenson,¹⁶⁶ and Cameron¹⁶⁸ have published methods for examination of canned foods. Excerpts from these publications are quoted below:

TECHNIC AND SYSTEM OF CULTURES

Condition of Container. After incubation and cooling to room temperature, the external condition of the can is classified as flat, flipper, springer, soft or hard swell. The condition of the seams is recorded, and a search for 'pin holes' made if acid products are under observation. Any other points are noted which may have a bearing on the final diagnosis, among which are code, make of can, and any regular marks or dents on the cover or on the side seam, as they may indicate the year of packing.

Incubation of the Can. Cans which are flippers, hard swells, or springers may not need incubation previous to examination, provided this condition is due to bacterial growth. Cans which are normal in appearance, however, should be incubated where the the question is one of sterility. On account of the possible presence of thermophiles, some of the cans should be incubated at high temperature, 55°C.(131°F.). Where there are sufficient cans, six or eight should be incubated at 37°C.(98.6°F.) and 55°C.(131°F.), and as fast as abnormalities appear they should be removed from the incubator and

168. Cameron. 1938. Assoc. Off. Agr. Chem. J. 21, 452-454; see also Idem, August, 1937.

subjected to examination. Pfuhl¹⁶⁹ advised keeping the can in the incubator for eight to 14 days to give opportunity for the anaerobic and facultative anaerobic bacteria to develop. After opening, the hole should be plugged and the can replaced in the incubator. This will allow the aerobic bacteria to develop. Another set of cultures should then be made. Weinzirl,¹⁷⁰ in his study of the bacteria in canned foods, incubated them for seven days at 37°C. (98.6°F.).

Cleansing and Opening the Container. Good practice is first to thoroughly scrub the can with soap and water. A good precaution is to follow this by wiping with alcohol. The final preparation for opening consists in flaming the end to be opened. Here it is highly desirable to hold the end to be flamed above the flame as convection currents are set up including distribution of the heat. If the can end is flamed from above, most of the heat is retained in the upper head space, and charring of the product occurs which may obscure the normal odor and taste. Flat cans are flamed until flipping occurs, as internal positive pressure is a desirable safeguard against laboratory contamination.

There is some hazard attached to the flaming of swelled cans. This is obviated to some extent by cooling in an icebox, then thoroughly wiping with alcohol and igniting.

The unopened container should be examined in order to determine whether the ends are flat, and the condition of the seams should be noted. The surface of the can should be carefully examined for evidences of rust. If the ends are concave, as they should be, the presence of vacuum is probably indicated and likewise the absence of bacterial spoilage.

Examination for Perforations. The presence of an undue amount of rust on the can indicates that pin holes and similar perforations may be present. While this condition may be determined with certainty after the can has been emptied, cleaned, and dried, some information may be secured before it is opened by going over it with a stiff, sharp-pointed needle.

Testing for Vacuum. If the container has bulged ends, there will, of course, be no need for testing for vacuum. If, however, the ends are concave, some information can be secured by determining the vacuum. The ordinary vacuum gauge is provided with a rubber cork, which thoroughly seals the can when the tip of the gauge is forced into the cover of the can. The vacuum gauge used in the author's¹⁷⁰ laboratory is provided with a side arm carrying a small stopcock into which cotton is forced. After the vacuum reading has been made, the stopcock may be turned to relieve the vacuum. The air that is sucked into the can is filtered through the sterile cotton, thus preventing access of extraneous bacteria.

OPENING THE PREPARED CONTAINER

Location of Aperture. Specimens of food products from the surface layers of the can are undesirable, at least for some products, because these areas receiving the greatest heat treatment are less liable to show viable bacteria. Therefore, the aperture through which specimens of food are removed should be so placed that a generous sample may be secured from the center of the can. Heat has penetrated more slowly to this area, and it is here that any possible viable bacteria may be found.

Instruments for Opening Containers. Among the various types of instruments used for opening the container are screw drivers, can openers, and a number of other blunt-edged tools. Most of them are objectionable because they may contaminate the product by forcing a piece of metal into the food, and thereby introduce bacteria and disturb the contents of the can. If the can is slack filled, this is not a serious problem, but in some products there is enough free liquor to cause it to flow out over the cover, especially if the can has been heated to sterilize the ends. A disk of metal should be cut from the sterilized cover with a sterile instrument made for the purpose, and the sample should be removed through this aperture. Then a larger portion of the metal may be cut out with the can opener, but the analyst should be very careful to make the opening at least one-half inch from the double seam on the can. The contents of the can may then be carefully removed and the can thoroughly washed and dried to enable further

169. Pfuhl. 1904. Ztschr. f. Hyg. u. Infektionskrank. 48, 121.

170. Tanner. 1936. Assoc. Off. Agr. Chem. J., August, 1936.

examination of the seams, if that is desired. Various devices made by the author for this purpose are shown in Fig. 5.

Protection of Container After Opening. After opening the can, the analyst may protect the top from contamination by placing a sterile cover of a Petri dish over it. The can proper then functions as the lower half of the Petri dish.

REMOVAL OF SAMPLE

Sample. The sample should consist of at least 15 grams of food material. If desirable, a second sample may be stored in a sterile container until the examinations have been completed, and a third sample may be used for enrichment.

FIG. 5. Showing various instruments used for removing samples for bacteriological examination from canned foods. A and B, devices for cutting a hole in a can; note the sharp cutting edges. C and D, devices for punching holes in cans. E, F, and G, hollow tubes of metal for removing specimens of solid food. These instruments are provided with plungers by which the sample is pushed from the tube.

Instruments Used. The type of instrument used is determined by the sort of food under examination. Liquid food products, such as thin soups or tomato juice, may be sampled with a sterile pipette made from ordinary glass tubing about 14 inches long and having fire-polished ends. With solid portions of food glass tubing is less liable to clog than is the ordinary pipette. Solid food materials, such as sweet potatoes and roast beef, may be sampled by forcing an instrument made like a cork borer through a one-inch opening in the top of the can and pushing it to the bottom of the can in order to secure as large a sample as possible. In the writer's laboratory special instruments provided with plungers force the sample out quickly into a sterile container,

which has been previously prepared to receive it. These instruments are 10 inches long and three-quarters of an inch in diameter. Several types devised by the author are shown in Fig. 5.

Enrichment of Contents of Can. There may be times when the conditions in the can are not entirely suitable for bacterial development. In cases where negative results have been secured in the bacterial examination, enrichment methods may be used for determining the presence of bacteria. These consist of creating a favorable environment by adding some culture medium to the can and subsequently incubating it. The addition of dextrose broth by means of a sterile syringe through a very small opening is a very satisfactory procedure since it contains the food products necessary for the development of most bacteria.

Organoleptic Examination. When the can has been opened, the odor and appearance of the contents should be noted. It is apparent that no statements can be made unless the analyst knows the normal product. That is the main reason why normal cans of the food should be sent with those suspected of being unsound.

Culturing. After the sample has been removed, as outlined above, it must be homogenized or otherwise prepared for inoculation into media. This may be done for solid foods, such as meats and sweet potatoes, in an electrically driven mixer, such as the Stevens Mixer¹⁷¹ or the Eskimo Whiz-Mix Disintegrator, both of which are the type of mixers used at soda fountains. Extra cups for each may be sterilized in advance.

In case of little information about the types of bacteria which may be present, the analyst should probably err on the side of too much data than too little. Therefore, a search for nonspecific microorganisms should be made as follows:

Inoculate dextrose tryptone broth for incubation aerobically and anaerobically at 37°C.(98.6°F.) and at 55°C.(131°F.). Do the same in dextrose tryptone agar in Petri dishes.

Nonacid Products—Vegetables, Meat, Fish, and Milk. Problems of canned-food technology require that emphasis be placed on spoilage types concerning which it is desired to know (1) the general morphology, (2) ability to form spores, (3) relation to oxygen, (4) relation to temperature, (5) general gas and acid-producing properties in the presence and absence of oxygen, each of which has special significance.

In addition to the more common media which may be used, if desired, are special media which have been devised for special purposes.

For Flat-Sour-Producing Bacteria. Platings in sufficiently high dilution should be made in dextrose tryptone agar containing brom cresol purple to give isolated colonies. This usually means that several dilutions are plated. This medium is also suitable for isolation of other aerobic and facultative anaerobic bacteria. For isolation of flat-sour-producing bacteria, incubators should be at 55°C.(131°F.). Cameron, Williams, and Thompson¹²³ described the changes which take place in this medium as follows:

“Flat-sour colonies are characteristic. The surface colony is usually round, measures from two to five millimeters in diameter, and contains a typical opaque central ‘spot.’ By reason of acid production in the presence of the indicator, the colony is set off by a halo of yellow in a field of purple. . . . Subsurface colonies are small and are not consistent as regards form. A more complete description of these bacteria is given in an earlier publication.”

For Thermophilic Anaerobic Bacteria. For thermophilic bacteria not producing hydrogen sulfide, liver broth should be used. The cultures are

171. The former is made by the Stevens Electric Company of Racine, Wis., and the latter by the Bersted Manufacturing Company of Fostoria, Ohio.

stratified with plain yeast water agar after inoculation. Cameron, Williams, and Thompson¹²³ described the changes which indicate presence of thermophilic bacteria as follows:

“Thermophilic anaerobes are manifest by the splitting of agar (that used for overlaying the liquid liver broth) and the presence of acid after incubation at 55°C. (131°F.) in liver broth stratified with agar or in deep dextrose yeast water agar tubes. Usually a ‘cheesy’ odor is apparent. In sulfite agar there may be a general blackening of the medium as a result of the production of hydrogen by the organism and consequent reduction of the Na₂SO₃ incorporated in the medium.”

Inoculations may also be made into corn meal-liver medium. The medium need not be steamed and requires no seal or other method of securing anaerobiosis. Thermophilic anaerobic bacteria free gas in this medium and may digest the medium.

For Thermophilic Anaerobic Bacteria Causing Sulfide Spoilage. Inoculate into Cameron’s sulfite agar medium in a culture tube to which a nail or clean iron slip has been added at the time of tubing.* Incubate at 55°C. Changes in this medium which indicate the presence of sulfide spoilage bacteria were described by Cameron, Williams, and Thompson,¹²³ as follows:

“In sulfite agar after anaerobic incubation at 55°C. (131°F.) the sulfide spoilage bacteria (or *Cl. nigrificans*) are detected through the formation of characteristic, distinct, blackened, spherical areas. There is no production of acid which is discernible through the use of indicator media. Owing to the solubility of H₂S and its fixation by the iron of the FeCl₃ incorporated in the sulfite medium, no splitting of the agar occurs. See also the report of Werkman and Weaver.”¹²⁸

For Putrefactive Spoilage Bacteria. Inoculate into beef heart-peptic digest broth, egg-meat mixture, or pork infusion. Evidences of growth will be those usually related to development of putrefactive bacteria: vigorous gas formation, darkening of the medium, and foul odors.

Acid Products—Tomatoes and Fruits. Spoilage types of microorganisms peculiar to these products are limited to yeasts and nonsporeforming, mesophilic, facultative anaerobic, acid-loving bacteria. Special media having tomato juice as a base have been useful for separating spoilage types from organisms unable to grow in acid substrate. A liquid medium, tomato-dextrose broth, consists of tomato juice and nutrient broth in equal parts with addition of one per cent of dextrose, sterilized with or without pressure. The solid medium is made by adding three per cent agar to the tomato-dextrose broth. This medium may be sterilized in flowing steam or prepared by adding the sterile agar solution to the sterile tomato-broth medium.

The procedure for these acid food products, therefore, resolves itself into the inoculation of aerobic tubes of tomato-dextrose broth, with the parallel inoculation of nutrient sugar broths, to be incubated at 35°C. (95°F.) to 37°C. (98.6°F.). After enrichment for plating and purification of tomato spoilage types, the tomato agar is desirable.

For detection of flat-sour-producing bacteria of the *Bacillus thermoacidurans* type, in tomato juice, the original juice or enrichment cultures

* The National Canners Association has since developed a medium containing ferric citrate instead of the nail or iron strip. This medium is described in Chapter 27.

The Examination of Spoiled Canned Foods: A Summary of Significant Features and Their Relation to the Cause of Spoilage.
(After Esty and Stevenson, 1925.)

Significant Features	NONACID PRODUCTS				ACID PRODUCTS	
	SPOILAGE FROM UNDERSTERILIZATION		Spoilage from Leakage of Can	Spoilage from Understerilization	Spoilage from Leakage of Can	
	"Flat Sours"	"Swells"				
Condition of container	Flat	Swelled	Swelled	Swelled	Swelled	
Microscopic examination of direct smears from can	Rods, with or without apparent spore formation, usually apparently pure cultures.	Rods, with or without apparent spore formation, usually apparently pure cultures.	Evident impure cultures usually containing cocci forms.	coid bacilli to very long rod forms.* Yeast?	Apparently impure cultures ranging from coccoid bacilli to very long rod forms. Yeast.	
Physical examination of contents	Usually sloppy in appearance; normal or sour odor.	Fermented appearance; sour or putrid odor.	Fermented appearance; sour or putrid odor; sometimes variations in appearance and color in different cans of the same sample.	Fermented appearance; sour, cheesy or alcoholic odor.	Fermented appearance; sour, cheesy or alcoholic odor.	
Cultures	Aerobic and anaerobic growth at 37°C. and 55°C. alone; no gas formation; usually evidence of spore formation in agar; microscopic examination should check direct smears.	Growth anaerobically with gas at 37°C. or 55°C., or both 37°C. and 55°C.; if aerobic growth occurs without gas formation at 37°C. and 55°C. alone the presence of a flat sour type is also suggested; microscopic examination should check direct smears.	Usually gas anaerobically and aerobically at 37°C. with or without growth at 55°C.; microscopic examination should show mixed culture and show presence of non-heat-resistant types.	Growth in special acid mediums at 37°C., with or without gas production; if no gas is produced reinoculate in sound cans to determine ability to produce swell; microscopically pleomorphic forms with possible presence of yeast.	Growth in special acid mediums at 37°C., with or without gas production; if no gas is produced reinoculate in sound cans to determine ability to produce swell; microscopically pleomorphic forms with possible presence of yeast.	
Seam examination	No leaks on pressure testing; seams and general condition of container good.	With "hard swells" leaks on pressure testing may be due to straining; seams should give indication of original sound condition.	Leaks on pressure testing; seams or general condition of can faulty.	No leaks on pressure testing; seams and general condition of container good.	Leaks on pressure testing; seams or general condition of can faulty.	

* This apparent impurity of culture is usually found to be due to the extreme pleomorphism evidenced by the group of organisms most significant in the spoilage of acid products.

should be plated in proteose-peptone-acid agar of Stern, Hegarty, and Williams.¹⁴⁹

Microscope Examination of Contents. Smears made direct from the canned product often give valuable information in the final correlation of results. Here, the ordinary carbolfuchsin or gentian violet stains usually give the results desired. Record is made of the apparent condition of the flora, whether pure or mixed, the presence of non-heat-resistant forms, of which the cocci are typical, and the presence of spores.

Examination of Cultures. Cultural observations are made on both aerobic and anaerobic tubes at 37°C.(98.6°F.) and 55°C.(131°F.), special note being made as to the presence of gas and acid and the temperature at which they are found. A microscope examination of positive cultures gives evidence as to the general morphology of types present, and the degree of purity of the original food contaminant.

When bacteriologic evidence indicates understerilization, cultures are purified by any of the common methods. After assurance as to the ability of the purified culture to form spores (in nonacid products), it is set aside for immediate or later classification.

In the event of an exhaustive study, the heat resistance of the spore is determined by the method of Esty and Williams. Finally, an attempt is made to reproduce spoilage by inoculation into sterile samples of the particular food from which it was isolated.

With acid foods, since thermophiles and sporeforming bacteria do not appear to enter as causative spoilage agents, observations are confined to the single temperature and the heat resistance tests apply only to vegetative forms.

Savage¹⁷² and Clark, Clough, Fellers, and Shostrom¹⁷³ have also outlined procedures for the examination of canned fish products. The former had to do with canned foods received at ports of entry in England, while the latter was concerned with canned salmon.

Autosterilization. Bacteriologists frequently encounter outbreaks of spoilage which have all of the earmarks of bacterial spoilage but from which no viable bacteria can be made to grow. If proper technic has been used and if several attempts have been made to demonstrate growth without success, it may be concluded that the bacteria which caused the spoilage died out—a phenomenon spoken of as *autosterilization*. The death of the bacteria may be considered to have been caused by an accumulation of products of metabolism, organic acids for instance. Frequently microscope examination will show the presence of many bacterial cells.

Cameron's Method for Sampling the Contents of Cans of Food Before Incubation. It is frequently desirable to make preliminary observations on the contents of cans of food before they are incubated. The problem is one of sealing the can after a small portion of the contents has been removed. Cameron, by correspondence, kindly gave the author the following method used in the laboratories of the National Cannery Association. Besides the usual materials and apparatus, some Goodyear Repair Gum for patching inner tubes and Goodyear Cold Patching Cement should be available. The repair gum should be cut into squares from one to one and a quarter inches on a side. These should be sterilized after wrapping in paper or being placed in some sort of container at 15 pounds' pressure for 30 minutes. The can should be prepared for opening in the usual manner. A hole is made in the can through which a portion of the contents is withdrawn. Then a fairly heavy film of patching cement is applied about the hole and ignited. When it has burned itself out a square of repair gum is removed from the sterile package, the cloth torn off, and the fresh surface applied to the opening of the can. When the can top has cooled, another application of patching cement may be applied about the gum. The can may then be incubated. Gas production during incubation will be indicated by bulging of the gum.

Crossley's¹⁷⁴ Method for Detecting Certain Sporeforming Bacteria in Canned Foods. This is a simple, inexpensive method developed for routine examination of canned foods for anaerobic, sporeforming bacteria causing spoilage. The medium finally adopted was

172. Savage. 1920. Gt. Brit. Food Invest. Bd., Spec. Rpts. 3 and 10.

173. Clark, Clough, Fellers, and Shostrom. 1923. Pacific Fisherman, Sept. and Oct.

sterile skim milk containing one per cent of peptone and .01 per cent brom cresol purple. It was heavily inoculated with the sample (from 1.5 to 2 grams) and incubated for three to four days at 37°C. (98.6°F.). Striking reactions, such as color change of the indicator, curd formation, and digestion or gas formation, permit detection and rough classification of anaerobic, sporeforming bacteria in food.

Another problem which has not been faced in the past by bacteriologists involves testing packs of canned foods. It probably enters all bacteriological work. In much laboratory work it may probably be ignored but not in work which involves determination of sterility, as may be the case with canned foods. It is the problem of contaminated plates and cultures. It is a problem which deserves more attention than bacteriologists have been willing to give it. This situation was emphasized to the author a few years ago when, in a cooperative investigation in which numerous control plates were made, many of them were contaminated with Micrococci. This work was done by mature bacteriologists and not by individuals who failed to realize the need for good technic. No problem is involved when a selective medium for some special organism is being used or where a plate count is being made, for appearance of a few extra colonies would make little difference since they would be only few in number. However, Williams and Clark¹⁰⁴ pointed out that in testing for sterility in any material, and especially where cultures are made on ordinary nutrient media and incubated at mesophilic temperatures, air-borne contamination may be very confusing to the bacteriologist and unjust to the packer. Examination of cans of food in the laboratory for sterility has always introduced the problem of what to do with plates made from the food which show but one colony. When such colonies are bacteria which are nonsporeformers with very low heat resistance, and are forms which are not indigenous to the product, they should be ignored. Bacteriologists should be careful before stating that a food product is not sterile. Multiple control plates and tubes should be made and not just a single one. A single control plate might remain sterile while several of the test plates receive contamination from the air. Such a situation would give misleading results.

General Examination of the Container. The container from which samples with organisms came should be examined. It must be shown to be sound and tight, else the value of the result of bacteriological examination may be seriously questioned. This should usually be done by an expert who is familiar with the structure of a can and is able to recognize serious defects. A few of the methods by which "leakers" may be detected will be mentioned with brief discussion. Bitting and Bitting summarized them as follows:

1. Tapping the can with a metal bar. Normal cans will sound dead. Savage¹⁷² used this method for judging the fitness of canned meats. He called it a "percussion" test.
2. Drop the can into boiling water. A stream of bubbles will come from the can if it leaks.
3. Immerse the can in water in a heavy closed jar and apply vacuum.
4. The Young vacuum tester will indicate the vacuum. Cans with no vacuum may inferentially be considered to be leakers.

5. The can may be closed with solder and tin and air forced into it. An apparatus is available with which cans may be "pumped."

Examination of Seams. In order to determine whether the double seam is tight, it may be examined after filing and taking apart. While only an expert should pass judgment on the quality of a seam, the technic is shown in Fig. 6.

Significance of Results of Bacteriological Examination of Canned Foods. The laboratory examination of canned foods, no matter how complete,

A.

B.

C.

D.

FIG. 6. Showing the technic for inspection of double seams on tin cans. (Courtesy of the American Can Company.)

A. Hold the can firmly and file a notch through the seam to the body of the can, using a sharp three-cornered file.

B. Starting at the notch, file through one thickness of tin around the entire seam.

C. Use the edge of the file to force down the cover hook.

D. Bend up the cover hook for observation and measuring the can hook. If the seam is loose, wrinkles will appear on the cover hook; the can hook should not be less than 1/16 inch lng.

would be worth very little without an accurate interpretation to the packer or layman who knows very little about the significance of such data. It goes without saying that microorganisms are undesirable in canned foods. The very object of the process is to seal the food in a container which would preclude exposure to bacterial action.

Nonsporeforming Bacteria. The presence of vegetative, nonsporulating bacteria in canned foods indicates that the cans were not processed properly or that the containers leaked. It is difficult to think of a vegetative bacterium which could withstand the cooks given to common canned foods. Having satisfied oneself that the cans were processed, the other explanation for the presence of these bacteria is leaky cans. This indicates the importance of a careful examination of the can for defects in manufacture. This should include complete stripping of the can. The nonsporeforming bacteria are usually forms of low heat resistance. Such bacteria might be drawn into the can if the seams were faulty when the can is in the cooling tank.

Aerobic, Sporeforming Bacteria. Aerobic, sporeforming bacteria are ordinarily less heat resistant than the anaerobic sporeformers. Their presence in canned food indicates either insufficient processing or leaky cans. In some cases, the presence of these bacteria may be due to underprocessing. Especially might this be true for foods processed in boiling water.

Anaerobic, Sporeforming Bacteria. Bacteriologists rather frequently find that non-thermophilic, anaerobic, sporeforming bacteria cause swells in canned foods. This type of spoilage is about as important as other types and is usually due to understerilization as well as leaky cans. Appearance of this spoilage justifies inspection of the can. A good example of the spoilage which may be caused by these bacteria is the so-called "putrefactive spoilage" of canned corn. This spoilage is distinguished from "sulfide spoilage" in that the latter is due to thermophilic bacteria.

Obligate Thermophilic Bacteria. The presence of obligate thermophilic bacteria in canned foods indicates understerilization, lack of proper cooling, or both. These organisms in flat cans which have not soured may or may not be of significance. They are probably of no significance provided the cans are stored at low temperatures. They are always potentially dangerous, for the can may be stored at sufficiently high temperatures to permit germination of the spores. Growth of obligate thermophilic bacteria indicates inadequate cooling.

Facultative Thermophilic Bacteria. The presence of facultative thermophilic bacteria also indicates inadequate cooling. Since facultative thermophiles are able to grow at room temperature, cans of food which contain them are quite liable to spoil when held for a long time.

CHAPTER 24

MICROBIOLOGY OF MISCELLANEOUS FOOD PRODUCTS

The difficulties of arranging a book of this nature has made it seem advisable to discuss the microbiology of several food products in a separate chapter.

Microbiology of Olive Oil. Freshly prepared olive oil, according to Chiappella,¹ may contain as many as 1,000 bacteria per ml. Six months after pressing, this number falls to between 350 and 800 per ml. in the sediment and from 10 to 40 in the supernatant layers. Mechanical purification by sedimentation was believed to explain reduction in numbers of bacteria, although it is not inconceivable that some species would die out in such an unfavorable medium. Acid oils were reported by Chiappella to be germicidal. Good olive oil should be neutral and, therefore, exert less action on microorganisms. Acid oils may result from bacterial fermentation of some constituents of the oil.

Chiappella observed survival of pathogenic bacteria in olive oil of good quality. Staphylococci, Streptococci, *Pseudomonas aeruginosa*, *Escherichia coli*, and *Eberthella typhosa* did not live longer than 40 to 50 days; *Vibrio comma* succumbed in 15 days. *Bacillus anthracis* lived for a few months. It was thought probable that all of the sporulating bacteria could live for months. From the above data, Chiappella advised that care be used in handling olives during and before pressing. Kurpjuweit² inoculated cultures of *Escherichia coli*, Staphylococcus, *Corynebacterium diphtheriae*, *Pseudomonas aeruginosa*, *Micrococcus ureae*, and *Eberthella typhosa* into olive oil. They lived, on the average, for about 10 days, and the period of existence of each organism seemed to be related to its ability to endure anaerobic conditions.

According to Pigulewski and Charik,³ olive oil is quite susceptible to attack by bacteria. They used strains of bacteria isolated from rancid butter. One strain caused deposition of a solid substance, which was considered to be ketostearic acid, formed from oleic acid. Rancidity of oil may, therefore, be due to bacterial decompositions. Guargena⁴ carried out experiments to determine longevity of bacteria in oils. Cottonseed, linseed, olive, sesame, almond, castor, and cod-liver oils, and butter and lard were used. *Pseudomonas aeruginosa* survived for 30 days in lanolin, almond oil, and cottonseed oil; in sesame and olive oils and butter, *Serratia marcescens* lost its vitality between the 10th and the 30th day. Similar results were secured with *Oidium albicans* and *Saccharomyces niger*. *Staphylococcus citreus* died out in castor oil after the 20th day. Feeding

of fat to guinea pigs reduced the intestinal flora, indicating, perhaps, an action on bacteria.

It is a difficult matter to rid oils of bacteria. They seem to be protected from the action of heat and survive amounts of it which are lethal in much shorter periods when organisms are suspended in another menstruum. This may be due to absence of water in the oil.

Bactericidal Properties of Oils. Just how significant this property of oils is, is difficult to determine. Mazzetti⁵ noticed that certain vegetable oils (olive, linseed, almond, soy, and castor) acquired definite, though weak, bactericidal powers when brought to high temperatures and cooled. Especially was this true of linseed oil. Tung oil and sardine oil were reported to be germicidal by Hirabayashi.⁶ Görtzen⁷ tested the following oils for their effect on bacterial behavior: cod-liver oil, olive oil, peanut oil, turpentine, yellow vaseline, lanoline, and eucerin. Most of them contained few bacteria which would indicate that bacteria could not grow readily in them. None of them except turpentine showed any inhibitive action on growth of bacteria. Arachis oil has been shown to be germicidal.

Microbiology of Peanut Butter. This is an important food, microbiology of which has not been studied to any extent. Questionable sanitary conditions of manufacture of peanut butter prompted Hall and Van Meter⁸ to investigate its microorganism content to determine whether it could be correlated with manufacturing procedures. They observed some bad conditions which in no way probably reflect the situation today. Since the days when Hall and Van Meter did their work, great improvements have occurred in the food-processing industry, some of which have occurred in the making of peanut butter. Hall and Van Meter examined 29 samples in none of which could coliform bacteria be demonstrated. In view of the fact that some of the samples were prepared under questionable sanitary conditions, it was assumed that peanut butter exerted a germicidal action on microorganisms or that they died out because foods were not available. Hall and Van Meter showed that germicidal action was possessed by arachis oil, the oil of the peanut, toward *Escherichia coli* and a few pathogens (*Eberthella typhosa*, *Salmonella schottmülleri*, and *Salmonella paratyphi*). Plate counts of peanut butter were not high, the larger proportion of samples showing less than 100 colonies per gram, only two samples showing over 5,000. Addition of water to peanut butter was claimed to invite spoilage.

Microbiology of Salad Dressings and Similar Products. Salad dressings are composed of materials which are subject to microbial spoilage. In addition to spoilage of this type there are others evidenced by separation, loss of consistency, rancidity, and discoloration. Gray⁹ called attention to the possibilities for introducing great numbers of microorganisms and to the several constituents which may be used by bacteria. He found

bacterial spoilage to be greater in mayonnaise which contained chopped pickles, pimientos, and similar materials than in plain mayonnaise. In the latter the principal inhibitor for bacteria is acid. Molds, however, may develop in presence of considerable acid. They do not cause much trouble in plain mayonnaise but are more likely to develop when starch and pectin have been added. Gray emphasized the fact that many microorganisms may reach the salad dressing from ingredients. An old egg or egg product might contribute so many bacteria that the preservative agents might not be able to keep them in control. In view of this possibility, it is wise to use only ingredients with a low microbial content. Increasing the acid content has been known to prevent development of large numbers of potentially active spoilage bacteria.

A common spoilage of mayonnaise is caused by fermentation of sugars by microorganisms. Its prevention is based on either elimination of these bacteria in ingredients or preventing their development.

Acidity has been mentioned by various investigators as the important factor in keeping mayonnaise. *Escherichia coli* was found to disappear from it in 24 hours at room temperature by Vladimirov and Nefedieva.¹⁰ When added in large numbers, however, it lived for six to seven days at room temperature and longer at 2 to 3°C. (35.6 to 37.4°F.). Other bacteria were also inhibited and destroyed by acid.

Bachmann¹¹ examined 15 brands of mayonnaise, 12 of other salad dressings, six of olive mayonnaise, and six of olive relish. With the exception of a few samples of homemade mayonnaise, only commercial products were studied, and the condition of all of the samples was good when the cans were opened. Of the entire number of cans, only four were found to contain anaerobes and these were nontoxic. The number of aerobic organisms varied from 0 to 17,400 per ml. The largest percentage of sterile cans was found among the salad dressings other than mayonnaise. These contained a starch paste, and it was thought that the heat used in preparing the paste and the acidity of the product were the chief factors contributing to sterility. The most probable source of contamination was considered to be the egg yolks. From 12 cans, sporeforming rods with morphological and cultural characteristics similar to *Bacillus subtilis* and *B. mesentericus* were isolated. *Escherichia coli*, when introduced into the various preparations, disappeared rapidly. *Bacillus subtilis* remained viable for a longer period of time. These products are susceptible to several types of spoilage. Anaerobic sporeforming bacteria cause, at times, a gaseous fermentation. It is necessary to use good vinegar to prevent much of the trouble. Iszard¹² described an organism which caused spoilage in a number of samples of mayonnaise. It was said to agree in all respects with *Bacillus petasites*. Inoculation experiments showed that this organism could spoil mayonnaise. Attempts were made then to determine the origin of the organism. These showed that it was present in the foundation paste; 10,000 colonies per

gram were counted. This product could not be sterilized by heat, and attempts were then made to determine whether the organism could be repressed by the addition of some special substance. It was found that lactic acid in a concentration of 1.75 per cent was sufficient to arrest bacterial development. An outbreak of spoilage in Thousand Island dressing was found by Pederson¹³ to be due to activities of *Bacillus vulgatus*. This organism came from the pepper and paprika. Pederson suggested two methods of protecting salad dressing from such bacteria: first, maintenance of such acidity that the organism cannot grow and second, sterilization of the ingredient which contains the offending bacteria. *Bacillus lekitosis*¹⁴ is another bacterium said to cause mayonnaise decomposition. Charlton, Nelson, and Werkman¹⁵ isolated *Lactobacillus fructivorans* from spoiled salad dressing. Such spoilage as just mentioned was attributed by Vladimirov and Nefedieva¹⁰ to improper preparation. They considered properly prepared mayonnaise to be hardly a favorable medium for development of microorganisms, especially on account of low pH (4.1 to 4.5). Vegetative forms cannot live in it but spores may live for a long time. *Escherichia coli* disappeared in 24 hours at room temperature. At lower temperatures, longevity would be much longer. This was the experience also with other bacteria and molds.

Microbiology and Preservation of French Mustard. Prepared mustard is subject to microbial spoilage if not properly handled. Much of the work on this subject has been done by Kossowicz.¹⁶ His results showed that freshly ground mustard may contain bacteria and spores of the *Subtilis-Mesentericus* group as it leaves the mill. Decomposition of mustard was said to be brought about by bacteria which were not active gas formers, although gas-forming bacteria are frequently present. Sterilization seemed to be an unsuitable method for making mustard keep. Kossowicz suggested that it was advisable to add some white mustard seed to the mash and to have higher acetic acid content, using garlic vinegar where possible. Kossowicz reported the presence of *Torulae* in mustard which had undergone spoilage. This mustard contained many gas bubbles and considerable alcohol. A number of species of bacteria belonging to the aerobic spore-forming group of bacteria were present. Campbell¹⁷ reported considerable fermentation in prepared mustard from bacterial contamination. Examination of jars revealed the presence of gas with a distinct hydrogen sulfide odor. The same organism which caused this spoilage was found in samples from empty barrels in which mustard had been stored. Campbell found the organism to be of the aerobic sporeforming type, probably quite like those described by Kossowicz. He believed the trouble to be due to contamination of the prepared mustard with some Chinese seed. Low acidity permitted the bacteria to develop. Prevention of this type of spoilage involves use of low-count raw materials, proper acidity, and heat treat-

ment after the product is in the jars. Bartarelli and Marchelli¹⁸ observed spoilage of mustard owing to growth of a member of the *Proteus* group. The spoilage was characterized by a peculiar odor and the appearance of gas bubbles. The organisms could be demonstrated by direct microscope examination. Bertarelli and Marchelli believed that the mustard had been infected by anchovies used in its preparation.

Copra. This is the dried meat of the coconut which has become an important commercial article in sections of the world where the coconut palm grows. Unless carefully prepared it is subject to mold deterioration. Moisture content of copra has been considered to be one of the important factors influencing deterioration. Fishlock¹⁹ stated that well-dried copra containing six per cent of moisture could be safely stored for long periods. Any superficial gray-green mold which appears on it may be considered to be harmless. The undesirable dark-colored molds cannot develop because of low moisture content. Fishlock's observations were made over a period of 62 weeks. Ward²⁰ agreed with Fishlock that copra with less than six per cent of moisture would keep. When moisture exceeds this amount it is liable to microbial deterioration. Action is most rapid at 12 to 15 per cent, when it is due both to bacteria (two species causing pitting and slime described) and to fungi (especially *Aspergillus flavus*, *Aspergillus niger*, and *Aspergillus tamarii*). At moisture contents approaching seven per cent growth is confined to the *Aspergillus glaucus* section and *Penicillium* spp. Brill, Parker, and Yates²² have greatly amplified our knowledge of this subject. They showed that bacteria played a minor role in the deterioration of copra, since usually there is too little moisture present to permit bacterial growth. When they do grow, it is usually on fresh copra which has a sufficiently high moisture content. Brill and his colleagues stated that copra which has less than 20 per cent of water is practically free from bacterial action; above this water content, the changes brought about by fungi are more important. Brill, Parker, and Yates found four molds on copra and coconut meat undergoing spoilage. The conidial masses differed in color, which permitted rapid separation of these species. In regard to the moisture required for their development, they arranged themselves in the following order: *Rhizopus* sp. (white mold), a mold occurring only on fresh meat and forming loose masses of white mycelium with many black sporangia; *Aspergillus niger*, a species occurring on copra with a relatively high water content; and, *Aspergillus flavus*, found most commonly on moldy copra; and *Penicillium glaucum*, usually found on copra with a low water content. These species were quite fully described, but the descriptions will not be reproduced here.

Microbial Spoilage of Coconut Oil. Few data have been published on this subject; there seems to be a general belief that microorganisms are of very little significance in this connection. Walker²¹ reported, however,

that they might have great significance in affecting the quality of coconut oil. Walker's work showed that bacteria and other fungi may cause much spoilage. According to Stokoe,²³ rancidity of coconut oil by *Penicillium* sp. is due to formation of methyl-amyl, methyl-heptyl, and methyl-nonyl ketones. The biochemistry of the deterioration will not be discussed here.

Microbial Spoilage of Cocoa Butter. This spoilage has become of economic importance in relation to the use of vegetable oils and fats in the manufacture of butter substitutes.

According to Batten and Bywaters,²⁴ cocoa butter is resistant to development of microorganisms and production of rancidity. They reported development of a mold in a large block of cocoa butter, weighing 28 pounds. When the block was broken a number of dull black spots were seen. These spots were studied and found to consist of hyphae of a mold. Cultural studies indicated the presence of *Penicilium glaucum*, a pink yeast, and a species of *Aspergillus*, believed to be *Aspergillus oryzae*. Small pockets of water were seen throughout the block, and it was believed that spores of the fungi had been introduced in this manner. The importance of water was proven by experiment; it was stated that little fear of molding need be entertained if cocoa butter is kept free from water. Discussion of this paper by several investigators showed that molding of fat was not an uncommon phenomenon.

CARBONATED BEVERAGES

Various factors in manufacture and use of carbonated beverages give these products considerable interest to the food bacteriologist and sanitarian. They were made at times in places of questionable cleanliness and were subject to microbial spoilage. The conditions under which these products are now made are probably satisfactory. These drinks consist of flavoring extract, sugar, water, and often some substance to produce a foam. That they are susceptible to the development of bacteria is indicated by the fact that they frequently become cloudy and ropy. Ropiness is caused by capsulated organisms which find these products favorable for their development. It is a difficult matter to disinfect a bottling plant after it has been infected with such organisms. All appliances must be kept absolutely clean and sterilized where possible. The author examined one bottle of root beer which was cloudy and ropy. The usual capsulated sporebearing organism was isolated. When inoculated into a sound bottle of root beer, the disease was reproduced. A committee of the American Public Health Association²⁵ deemed it advisable to study methods for controlling the microbiological condition of such beverages and the bactericidal value of certain procedures in their preparation.

Investigations were undertaken by Young and Sherwood²⁶ to determine whether or not pathogenic organisms could withstand the unfavorable environment in bottled carbonated beverages a sufficient length of time to reach the consumer. It was found that the number of organisms in the

26. Young and Sherwood. 1911. *J. Ind. Eng. Chem.* 3, 495.

beverages examined was extremely small, except for those which had been introduced experimentally. There was a decided reduction in number of such organisms after standing 244 hours uncarbonated. There was a very marked reduction in numbers of all three organisms introduced, and especially of *Eberthella typhosa*, owing to conditions existing in the carbonated bottles. The organisms were not completely killed during the time of the entire experiment. *Serratia marcescens* and *Escherichia coli* seemed to be somewhat more hardy than *Eberthella typhosa*. Undoubtedly the longevity of *Eberthella typhosa* depends to a great extent upon the virulence of the organism; as the results above show that some of the organisms will live longer than the beverage is normally on the market, the manufacturer should not depend upon the sterilizing effect of the carbon dioxide and other substances used. From the observation that the hardy individuals can resist these adverse conditions for a considerable length of time, it is apparent that a satisfactory water should be used and every attempt made to maintain cleanliness and prevent contamination during manufacture and storage. Allen *et al.*²⁷ presented the results of a sanitary survey of the soft-drink industry of the state of Kentucky. The methods employed in the survey were similar to those developed in milk inspection. Sanitary inspections were made of the plants where these products were prepared, including an investigation of the equipment used. Especial attention was given to the methods employed in washing bottles. The necessity for thorough sterilization of the bottles or other containers was emphasized. It was recommended that they be kept in live steam from 30 to 40 minutes and any subsequent contamination guarded against. Chemical and bacteriological examinations of the water used in the manufacture of soft drinks showed that many of the plants were using water which needed purification by filtration or sterilization. The results of the bacteriological examination of the soft drinks are presented in detail; some of the conclusions drawn were that the bacteriological count of the finished product is not a correct index of the sanitary conditions existing during manufacture, and that although carbon dioxide gas is somewhat germicidal, it cannot be relied upon as a sanitary safeguard since it does not inhibit or kill all microorganisms.

Members of *Bacillus subtilis* group were commonly found by Gaucher and Geors.²⁸ When *Escherichia coli* and *Eberthella typhosa* were inoculated into lemonade, they increased rapidly for 15 days and then fell off in numbers. Koser and Skinner²⁹ inoculated carbonated beverages with several pure cultures. *Eberthella typhosa* and *Salmonella schottmülleri* were killed more quickly than *Escherichia coli*. Sporeforming bacteria, as evidenced from data secured with *Bacillus mesentericus* and *Bacillus sporogenes*, were quite resistant. Similar experiments were carried out by Ynovskii³⁰ wherein unpasteurized, nonalcoholic drinks were inoculated with *Eberthella typhosa*, *Shigella dysenteriae*, and *Salmonella schottmül-*

leri, several strains each. The organisms survived for times not longer than three to four days, most of them dying out before.

In an investigation of the effect of carbon dioxide on bacteria, results not unlike those quoted from publications of others, were reached by Donald, Jones, and MacLean.³¹ They stated that one of the reasons for adding carbon dioxide to beverages was its definite germicidal power. Beverages produced under very unsanitary conditions never contained *Escherichia coli*. This indicated that some factor was operating which was detrimental to bacteria. To determine this factor they bottled ginger ale in the following ways:

1. Plain without gas.
2. Under high pressure of nitrogen.
3. Under moderate pressure of carbon dioxide.
4. Under high pressure of carbon dioxide.

The authors stated that reductions in bacterial population were due to carbon dioxide and not to the pressure. Experiments were then carried out with ginger ale inoculated with *Eberthella typhosa* with different amounts of carbon dioxide. Uncarbonated beverage was found to allow a rapid growth of bacteria. Donald, Jones, and MacLean pointed out that a beverage carbonated and prepared under proper conditions, improved with age. That the germicidal effect of carbon dioxide is not due to pressure, since pressure in itself seems to have little influence on the organisms, except over a longer period of time and in a degree greater than that employed in commercial practice, is claimed by Levine.³²

Stokes³³ found a variable number of bacteria in these beverages. The variable number was attributed to dirty bottles. He called attention to the fact that small portions of the contents were usually left in the bottle. In these, large numbers of bacteria grew to have significance when the bottles were filled. Extensive studies have been carried out at Iowa State College by Levine.³² Of 69 samples, 12 per cent contained over 100,000 bacteria per ml. These organisms were said to have originated in the water used, the sirup, and unclean apparatus. General sanitation and sterilization were offered as remedies. Similar data have been reported by Kilcourse.³⁴ In a study of the sanitary features of the dispensing of 'soft' carbonated drinks, he determined the bacterial content and the presence of *Escherichia coli*. The counts ran from two to 500 colonies per ml. with one having a count of 100,000. Five out of 25 specimens gave positive presumptive evidence of the presence of *Escherichia coli*. Forman³⁵ found few bacteria in 60 samples of soda water.

The importance of the carbonated-beverage industry in Chicago caused the Health Department through its Bureau of Food Inspection to study the various phases of the industry. Kilcourse³⁴ reported the efforts of the Health Department to improve conditions. The first problem was to

secure a sterile bottle. After study through a special committee appointed for the purpose, the following approved methods of bottle sterilization were adopted:

1. *Machine Alkali*. (a) Minimum proportion of caustic alkali to soda ash, 2 to 1; (b) use minimum charge (1.5 pounds per cubic foot water); (c) make solution 12 hours before use, to allow mixing; (d) minimum alkali reckoned as NaOH (sodium hydrate) always to equal, or exceed, 1 per cent (10 grams per liter); (e) clean machine out thoroughly at least once each week.

2. *Wash and Rinse Water*. (a) Water supply must be safe; (b) water must have sufficient pressure to effect complete rinsing, no alkali left in bottles; (c) spiral rinsing stream suggested as more effective than direct stream.

3. *Machine*. (a) Minimum temperature of caustic solution always to be at least 48.9°C. (120°F.)—automatic thermoregulator suggested; (b) maximum speed to expose bottles *within* the caustic solution at least 10 minutes; (c) examine each brush daily; keep brushes overnight, or when not in use, in moderately strong soda solution; (d) be certain that the caustic solution is not diluted by leakage or seepage.

A score card was devised for use in sanitary inspections of bottling plants. The data which are of interest at present are those secured from bacteriological examination of so-called soft drinks. In order to determine the general bacteriological condition of these products, 25 samples were collected at random for analysis. It was found that the bacterial count varied between two and 500 colonies per ml., with one sample showing a plate count of 100,000 per ml. Eliminating this specimen, the average count of the other 24 was 100 bacteria per ml. Five of the samples showed *Escherichia coli*. These data are interesting in relation to Knapp and Buchanan's³⁶ statement that a satisfactory nonalcoholic beverage could be made which would have not more than 100 bacteria per ml. and be free from the members of the coli group.

Discussion of the microbiology of such products as carbonated beverages might well end with a brief review of the effect of carbon dioxide as such on bacteria. D'Arsonval and Charrin³⁷ reported that a pressure of 50 atmospheres of carbon dioxide sterilized cultures of *Pseudomonas aeruginosa* in six to 24 hours (Koser and Skinner). Similar results were published by Larson *et al.*³⁸ Prucha and Brannon,³⁹ in a study of carbonated ice cream, reported that carbon dioxide under the conditions under which they worked, did not kill pure cultures of bacteria. The investigations of Bruschetti,⁴⁰ Frankel,⁴¹ Altana,⁴² Grossman and Mayerhauser,⁴³ Pasteur and Joubert,⁴⁴ Buchner,⁴⁵ Liborius⁴⁶ and others quoted by Allen seem to show that carbon dioxide exerts a selective action on bacteria. Some are completely killed off, while others are not harmed and will even increase in numbers in its presence. Whether carbonated beverages con-

tain many or few microorganisms, then, depends on the initial contamination. Corper⁴⁷ reported that three per cent of carbon dioxide had inhibitory effects, while 15 per cent had bactericidal powers. These data are of special significance in the dairy industry where the problem has been studied by Rettger⁴⁸ and others.

Deterioration of Carbonated Beverages by Yeasts. The saccharine nature of carbonated beverages, the fact that the closed bottles are not pasteurized, and the lack of marked germicidal properties by the constituents make them susceptible to the attack of microorganisms.

McKelvey⁴⁹ found yeasts to be very frequent causes of spoilage of carbonated beverages. Of over 1,500 samples examined during a period of two years, about 85 per cent had spoiled as a result of yeast growth. Of 132 samples of sugar obtained from 125 bottling plants in 28 states, 62 were found to contain yeasts (47 per cent). Carrot sugar, saturated with calcium sulfate, was found to be suitable for the development of yeast spores and the production of large quantities for experimental work. Yeast spores obtained from carrot calcium sulfate agar were tested as to their resistance to heat in sirups of various concentrations of cane sugar. In general, the higher the concentration of sugar the longer was the time required to kill the yeasts under examination.

Bacterial Spoilage of Carbonated Beverages. As stated above, carbonated beverages usually contain bacteria. Most of them seem to be dormant, but occasionally they may grow and cause spoilage. A rather common defect, owing to growth of bacteria, is development of rope. This deterioration is quite similar to that which occurs in bread and milk. The organism which causes it is a capsulated, aerobic sporeformer. Prevention of this spoilage depends on thorough cleaning of the bottling plant and a destruction of spores of spoilage bacteria.

Microbiological Analysis of Carbonated Beverages. A committee of the American Public Health Association⁵⁰ proposed the following procedure: At least two representative bottles of any particular flavor shall be taken per three-hour period of plant operation or of stock at point of sale. Each bottle shall be opened aseptically and the top given a light flaming. Remove a sample with a 10-ml. pipette with one-ml. markings; plate one-ml. portions and .1-ml. portions in nutrient agar, wort agar, or Sabourard's agar. Incubate three days at 28 to 30°C. (82.4 to 86°F.). Report microorganisms as mesophilic bacteria, yeasts, and molds per milliliter of beverage.

NUT MEATS

These have become a sanitary problem owing largely to the fact that they have been shelled and handled under very unsatisfactory conditions. They are not only eaten as such but are added to other foods, such as frozen desserts, the bacteriological quality of which is guarded carefully. Should they harbor *Escherichia coli*, the coliform test could not be used

47. Corper. 1921. Amer. Rev. Tuberc. 5, 562.

for determining the sanitary quality of a food to which they are added. For these reasons much bacteriological work has been done on nut meats during the last few years. Weinzirl⁵¹ examined 600 samples of nut meats for presence of *Escherichia coli*. He reported presence of this organism on .5 to two per cent of the samples tested. He concluded that nut meats were not an important source of *Escherichia coli* found in candies. In an attempt to learn more about the bacteriological quality of ingredients of ice cream Newman and Reynolds⁵² found a low bacterial content on the samples which they examined. A similar desire on the part of Prucha⁵³ prompted examination of nut meats. Six of 20 samples were free from microorganisms; five others had bacterial counts greater than 30,000 per gram; two showed very high numbers. Mold spores were found to be present in a few samples. *Escherichia coli* was present in four samples. This organism was believed to come from the hands of those who shelled the nuts. DePew⁵⁴ suggested greater care in handling shelled nuts and wearing of rubber gloves by the shellers. Since nut meats often show evidence of contamination by human beings, Tracy and Brown⁵⁵ studied methods for improving their sanitary quality. The best treatment studied was to dip the nuts into hot (180°F.) sucrose solution for 30 to 60 seconds, then dry for 2.5 minutes in a 250°F. oven. The nuts should then be kept in cold storage, preferably in glassine bags, until used. Nuts treated in this way contained less than 100 bacteria per gram and were free from *Escherichia coli*. Different methods of soaking nut meats raised their moisture content and injured their texture. Iverson⁵⁶ believed that roasting the nuts in butter improved their flavor. Such a practice would also lower their microbial content considerably.

Clark and Booth⁵⁷ observed quite a wide variation in bacteria content among different samples and different kinds of nut meats. Exposure of meats during sale tended to raise their bacterial content. Those which were sold in cellophane bags were generally better than those sold in bulk. Pecans gave the most variable results, the highest counts being obtained from a few samples. Mixed nuts gave consistently higher average counts. Aerobic sporeforming rods were the most common type of organism encountered. Seven, or 3.12 per cent, of 224 samples gave cultures of *Escherichia coli*. Staphylococci were present in 54, or 24 per cent, of 224 samples examined. Tests were run to determine characteristics of these organisms. While the results of the tests were not conclusive, they do indicate that some of the staphylococci isolated may be of sanitary significance. Artificially contaminated nut meats stored at room temperature contained viable cells of *Eberthella typhosa* for three to four weeks, *Escherichia coli* for five weeks, and *Staphylococcus aureus* for nine to 10 weeks.

More comprehensive investigations have been carried out by Wenzel and Black⁵⁸ who examined black walnuts, English walnuts, pecans, almonds, pistachio nuts, cashew nuts, and peanuts from six ice cream plants and one retail store, using dextrose agar incubated at 37°C. (98.6°F.) for six samples, and dextrose agar and tryptone agar incubated at 37 and 32°C. (98.6 and 89.6°F.) for 14 samples. Incubation at 32°C. increased the total number of bacteria and predominating species more than modification of the medium; glucose tryptone agar at 32°C. consistently yielded the highest counts. Aerobic bacterial counts varied with different nut meats; anaerobic and thermophilic counts were negligible. Gas was obtained in lactose or brilliant green bile broth with five samples, but *Escherichia coli* was not present. Yeast and mold counts increased with poor storage conditions. Nut meats treated by canning in sugar syrup or roasting in butter and salt gave lower counts, and those exposed in poor containers to air, dust, and room temperature gave higher counts. *Bacillus*, *Actinomyces*, *Streptococcus*, *Sarcina*, *Micrococcus*, *Flavobacterium*, *Lactobacillus*, and *Leuconostoc* species were isolated; none were pathogens. Twenty of 30 species of predominating organisms identified were Bacilli. *Bacillus subtilis* being present in 50 per cent of the samples.

No coliform bacteria were found by Ostrolenk and Hunter⁵⁹ on any of 34 samples of nuts in the shell, the samples having been shelled aseptically. *Escherichia coli* was present in all but two of 11 varieties in from four to 68 per cent of 548 samples representing 200 retail market samples, 234 domestic shelling-plant samples, and 114 imported samples from eight countries in Europe and the Orient and from Mexico. Artificially contaminated nut meats stored at room temperature contained viable *Escherichia coli* for approximately 68 days. Examination of 102 samples of nut meats for biochemical Colon-Aerogenes types indicated that when large numbers of *Escherichia coli* are present correspondingly large numbers of *Aerobacter aerogenes* and intermediates are found.

To evaluate the sanitary significance of coliform bacteria on nut meats, Ostrolenk and Welch⁶⁰ attempted to ascertain the origin of these bacteria on pecan meats. They found shell stock to harbor coliform bacteria. Tempering water was also highly polluted, *Escherichia coli* being demonstrated in some cases in .0000001 ml. Ostrolenk and Welch showed that chlorination markedly reduced the coliform bacteria. This along with general sanitary procedures were considered to be desirable.

Ostrolenk and Welch's⁶⁰ Method for Bacterial Examination of Pecan Meats. Fifty-gram samples of pecans were washed in 50-gram amounts of sterile water and the washings inoculated in decimal dilutions into standard lactose broth. Cultures showing gas formation after 24 hours incubation at 37°C. (98.6°F.) were streaked on eosin methylene blue agar plates.

Association of Official Agricultural Chemists⁶¹ Method for Microbiological Examination of Nut Meats and Nut Products. This method was adopted in 1942 as tentative until it could be subjected to critical examination.

61. Assoc. Off. Agr. Chem. J. 25 (1942), 109-110.

Place in sterile 125-ml. bottle, fitted with a ground-glass stopper, 50 grams of nut meats, comprising particles selected at random from sample or subsample. Use strict aseptic precautions in opening the package, carton, jar, or other receptacle holding the sample, and in transferring meats to sterile bottle use a metal spoon sterilized by immersion in alcohol followed by heating by direct flame.

Add to nut meats 50 ml. (or 50 grams) of sterile water. Shake vigorously three minutes or longer, if necessary, to effect a thorough washing of the nut meats. Following this agitation, allow specimen to stand about five minutes, again shake vigorously, and withdraw quantities of the suspension for direct inoculation of culture media and for the preparation of serial dilutions.

CULTURE TECHNIC

Transfer to series of fermentation tubes of lactose broth two-ml. portions of original washings and of 1:10 and 1:100 dilutions of the washings. (In view of dilution originally effected by washing 50 grams of nut meats in 50 ml. of water, a two-ml. inoculum is required in each case to permit interpretation of results in terms of washings of 1, .1, and .01 gram of nut meats.) Incubate lactose broth cultures 24 hours at 37°C. (98.6°F.) and examine for gas production.

Inoculate a series of plates with two-ml. portions of 1:100 and 1:1000 dilutions of the washings. Pour plates with nutrient agar and incubate for 48 hours at 37°C. Determine total aerobic counts and express as numbers per gram of nut meats.

From the lactose broth cultures showing gas, streak plates poured with Levine's eosin-methylene-blue or Endo agar. Incubate plates 24 hours at 37°C. Examine the eosin-methylene-blue or Endo agar plates for colonies of organisms of the coliform group. Select representative colonies for transfer to nutrient agar slants. Incubate the slant cultures for 24 hours at 37°C. Purify cultures for further study. Ascertain the biochemical reactions of the purified cultures by the following tests: Kovac's test: indol production; methyl red (M.R.); and Voges-Proskauer (V.P.) tests; Koser's sodium citrate test: utilization of sodium citrate as sole source of carbon.

Follow the procedures recommended in Standard Methods of Water Analysis, eighth edition (1936), of the American Public Health Association, under Appendix 1, Section XVII (Differentiation—Coli-Aerogenes Group Organisms).

The biochemical types encountered usually fall within the following six classes:

Indol	M. R.	V. P.	Citrate	Type
+	+	—	—	<i>Escherichia coli</i>
—	+	—	—	<i>Escherichia coli</i> (atypical)
+	+	—	+	<i>Escherichia freundii</i> (coli intermediate)
—	+	—	+	<i>Escherichia freundii</i> (atypical coli intermediate)
—	—	+	+	<i>Aerobacter aerogenes</i>
+	—	+	+	<i>Aerobacter aerogenes</i> (atypical)

Coliform organisms giving other sets of reactions may occasionally be encountered.

In a later report in the same journal, Ostrolenk⁶² stressed study of the presence of *Escherichia coli* on nut meats since this organism is commonly used as an indicator of pollution of fecal origin. The presence of this organism on such products might indicate that they are contaminated and might be potential sources of disease. He compared the results of washings from whole nut meats with the washings from thoroughly ground-up specimens and the washings of 10-gram subsamples with the washings of 50-gram subsamples. Results of these investigations were not published.

Germicidal Action of Vegetable Juice. Certain vegetable juices have been shown to be bactericidal. Whether this action is due to a single substance or to a composite has not been demonstrated.

62. Ostrolenk. 1942. J. Assoc. Off. Agr. Chem. 25, 736.

Onion Juice. The chief volatile constituent of onion juice is generally believed to be allyl sulfide. Walker, however, quotes results of experiments by others to show that this is in error and that a disulfide is involved. Walker, Lindegren, and Bachmann⁶³ reported the presence of fungicidal substances in onion juice. One of these substances is neither removed nor broken down by heat and another, which is volatile, passes off from extracted juice within a few hours at room temperature. While Walker, Lindegren and Bachmann's work was done mainly with higher fungi, others, as indicated below, have extended it to common bacteria.

Lovell⁶⁴ observed a bactericidal effect of onion vapors. The action was not as strong as that of garlic vapors and is more easily exhausted. Temperature seemed to have influence because bactericidal emissions from one gram of onion increased from 10°C.(50°F.) to 37°C.(98.6°F.). He worked with *Mycobacterium smegmatis*, *Bacillus subtilis*, *Bacillus mycoides*, and *Serratia marcescens*. Results of a more comprehensive investigation on onion juice were published by Fuller and Higgins.⁶⁵ Two varieties of onions were employed in which the influence of different concentrations of onion juice on bacterial growth was studied. The bacteria tested belonged to the following groups or genera: *Bacillus subtilis*, coliform, *Pseudomonas*, *Salmonella*, *Proteus*, and *Staphylococcus*. The *Bacillus subtilis* group was the most susceptible to the inhibitory power of the juice. Species in the genera *Proteus*, *Staphylococcus* and *Salmonella* were alike in their tolerance, and were slightly more resistant than those in the *Bacillus subtilis* group. Coliforms and those belonging to the genus *Pseudomonas* were the most resistant.

Age, variety, and storage of the onions had no apparent effect on the potency of the juice expressed from them later. Filtration through a Seitz filter produced a potent juice. Intermittent sterilization by steam weakened the toxic property, and sterilization by steam under pressure destroyed most of it. The pH of the juice did not appear to influence its toxicity.

Escherichia coli produced acid but no gas in the juice. *Aerobacter aerogenes* produced acid and an abundance of gas. The behavior of "intermediates" depended upon whether they approached *Escherichia coli* or *Aerobacter aerogenes* the more closely in their general reactions.

Garlic Juice. Early general observations indicated that garlic juice might be harmful to bacteria as were a few other vegetable juices. Walton, Herbold, and Lindegren⁶⁶ reported that garlic vapors have a bactericidal effect. *Mycobacterium butyricum* and *Mycobacterium smegmatis* were more susceptible to the bactericidal effect of garlic vapors than *Escherichia coli*, *Serratia marcescens*, or *Bacillus subtilis*. Boiled and autoclaved garlic were not germicidal. Matsumosuke and Shin-ichi⁶⁷ also showed the antiseptic value of constituents of garlic. Their exact chemical nature does not seem

to be known. Vollrath, Walton, and Lindegren⁶⁸ provisionally identified the bactericidal substance of crushed garlic and onions as acrolein or crotonaldehyde. To confirm this Ingersoll, Vollrath, Scott, and Lindegren⁶⁹ tested the bactericidal properties of crotonaldehyde. Vapors from about one-per cent solutions of either acrolein or crotonaldehyde will poison the surface of agar plates.

Horse-radish. This root has also been found to contain bactericidal substances. Foter and Golick⁷⁰ found that the bactericidal effect of the vapors of horse-radish were most pronounced at 37.5°C.(99.5°F.), decreasing with lowering of the temperature. Horse-radish vapors were much more bactericidal than those of onion or garlic but were more quickly exhausted than those of garlic. The bacteria used were ordinary species. Foter later reported that the active principle in crushed horse-radish is allyl isothiocyanate. This compound, together with methyl isothiocyanate and ethyl isothiocyanate, exhibits bactericidal effects on a variety of microorganisms when tested by several methods. The bactericidal efficiency of the oils can be more accurately determined by dilution in agar or by the preparation of aqueous suspensions than by exposure of agar plates to the vapors from similar dilutions. Allyl isothiocyanate is a pungent volatile oil which irritates the eyes and burns the skin.

SPICES

Spices are of interest to microbiologists for two reasons. Some of them are appreciably germicidal and destroy or repress bacteria; others may harbor many microorganisms among which may be just the species that food technologists attempt to keep out of foods. The former aspect of spice microbiology has been discussed in Chapter 1 and will not be considered here. The latter problem was not appreciated until Jensen, Wood, and Janson⁷¹ showed the significance in food-preservation industries of contaminated spices. High total and spore counts at 37°C.(98.6°F.) and 48°C.(118.4°F.) were observed in all of four samples of black pepper (coarse and fine), white pepper, and coriander. The black pepper showed the highest contamination with a total count of 47,000,000 and a spore count of nearly 2,000,000 per gram at 37°C.(98.6°F.). At 48°C.(118.4°F.) the counts were 44,000,000 and 400,000, respectively. The white pepper contained a lower number of bacteria and the coriander the smallest number. Having shown that spices are highly contaminated, the next problem was to study methods for sterilizing them. Two methods were attempted, ultraviolet light and steam pressure. Results with the former method were not encouraging because of the fact that this type of energy does not penetrate. Sterilization under steam pressure gave promising results. Cameron⁷² reported wide variation in the bacterial content of spices even of the same kind.

72. Cameron. 1937. The Canner 84, No. 12, Pt. 2, 96.

These observations stimulated much work in the laboratories of the National Canners Association by Yesair and Cameron.⁷³ A personal visit to a spice-manufacturing plant and observations on methods of handling indicated that the problem is mainly one of removal of the contaminating bacteria, particularly those which may cause deterioration in foods to which they are added. No evidence exists that any health hazard is involved. Bacteriological examination of 127 samples of spices from several sources showed marked variations in bacteria content of similar spices. Black pepper was the most heavily contaminated spice, the counts of seven samples ranging from 1,200,000 to 16,300,000 per gram. The numbers of molds, acid-tolerant bacteria, and aerobic mesophilic bacteria were also high, but thermophilic aerobes were few. Putrefactive anaerobic bacteria were not found in 116 samples. Cloves contained few microorganisms. Many of these bacteria could be eliminated by screening methods. Two large tables were published by Yesair and Williams⁷⁴ in which counts of many spices were given.

Fabian, Krehl, and Little⁷⁵ observe counts of bacteria in market samples of spices which ranged from 0 to 67,000,000 per gram. Peptonizing bacteria were present in over 10 per cent of the total number. Samples of oils of spices, 50-per cent emulsions of spices and spices in sugar-soluble base were found to be sterile.

Bactericidal action of spices has been discussed on page 44.

Sterilization of Spices. This, apparently, is the only satisfactory method of meeting the problem. Little progress seems to be probable from efforts to control contamination at the source. Consequently, those who have had to meet the problem have resorted to special treatment of the spices. Various substances have been used under various conditions. Yesair and Williams⁷⁴ observed that moist heat was an effective means of sterilizing black pepper, which was used in their experiments because of its high contamination. Even though they observed a loss of some 10 per cent of potency of the spice by heating at 15 pounds' pressure for 15 minutes, this was more than compensated by spoilage reduction.

A method of sterilizing spice by ethylene-oxide *in vacuo* at an elevated temperature was patented by Griffith and Hall⁷⁶ and described by Hall.⁷⁷ When studied by Yesair and Williams⁷⁴ with black paper, the method gave practical sterility. A few other methods were studied by these investigators but the results were not significant. Ultraviolet light was unsatisfactory. Griffith and Hall's method subjects the material to high vacuum and then exposes it to undiluted ethylene-oxide in a concentration of not less than three quarters of a pound per 35 cubic feet at a temperature not less than 21.1°C.(70°F.) to 26.6°C.(80°F.) for at least two and one-half hours.

Microbiological Examination of Spices. Presence of not only large numbers of microorganisms in spices but especially types which have been shown to cause spoilage makes it desirable to analyze them. The methods for this are quite like those used for other foods. The culture media should be known to favor the organisms being determined. The Committee on Microbiological Examination of Foods of the American Public Health Association has published recommended procedures^{52a} based largely on well-known procedures for determining presence of certain types of organisms in canned foods, sugar, and starch.

Samples. Take a 50 gm. sample from each of three containers and pack into glass jars for transmission to the laboratory.

Preparation of Samples. Weigh the spice after thorough mixing on a sterile paper or directly into a flask. Owing to differences in bacterial content the committee recommended the following amounts:

Whole spices.....	10 gm.
Bulky spices.....	2 gm.
Ground spices.....	1 gm.

Add sterile water to the spice sample up to the 100-ml. mark if a dilution flask is used or bring the weight of the sample and flask up to 100 gms. Shake vigorously for five minutes and allow to settle before specimens for plating are removed.

Bacteriological Examination. Numbers of various types of microorganisms should be expressed per gram of spice.

Total Bacterial Count. Plate in the usual manner 1 ml. or more of the suspension prepared above, using any of the ordinary agar media. The committee recommended Brom-Cresol Purple Tryptone Agar medium or nutrient agar with incubation for 48 hours at 37°C. or 55°.

Acid-Tolerant Microorganisms. Plate with wort agar and incubate at 25°C. for five days.

Detection of Spores. Vegetative cells are killed by boiling the suspension for five minutes. Plate 1-ml. portions on Brom-Cresol Purple Tryptone Agar medium and incubate for two days at 37°C. and 55°C.

Putrefactive Anaerobes. Use liver broth medium and inoculate as directed in Chapter 23 where these organisms are sought for in canned foods.

Thermophilic Anaerobes. In food microbiology two types are of interest, those producing hydrogen sulfide and those producing none of this gas. Procedures are given for determining presence of these species in canned foods in Chapter 23, and in starch and sugar in Chapter 19.

Flavoring Extracts. Some of these have been found to contain many bacteria. Prucha⁵³ found *Escherichia coli* in some color solutions but not in flavoring extracts. DePew⁵⁴ recommended pasteurization to rid them of bacteria. Tracy and Brown⁵⁵ attempted to heat color solutions and flavoring extracts before use.

CHAPTER 25

MICROBIOLOGICAL METHODS OF ASSAYING FOODS FOR VITAMINS

BY FRED W. TANNER, JR., PHD.

Use of microorganisms for determining nutritional properties of foods has opened new methods of research. Bacteria and yeast nutrition studies have led to solution of many vitamin problems and have aided in their discovery and isolation. During the last few years they have become another tool for nutritionists because of their ability to replace animals in biological assay of certain foods for vitamins of the B-complex.¹

Animal and vegetable extracts have long been incorporated in bacteriological media either to insure growth or to maintain maximum rates of multiplication and fermentation. Requirements of bacteria for certain accessory substances led Wildier in 1901 to suggest the existence of a substance indispensable for development of yeasts which he called "bios." A few years later Funk introduced the term "vitamine" to designate factors required by animals for proper growth and development. After animal experiments had shown "vitamines" to consist of several substances capable of curing or preventing certain pathological conditions, much effort was expended on their isolation and chemistry and on whether other forms of life needed them. Parallel investigations on bacterial "growth factors" were being conducted. For reviews of this phase, the reader is referred to Tanner,² Miller,³ Peskett,⁴ Koser and Saunders,⁵ Williams,⁶ Fulmer,⁷ Barker,⁸ and Robbins and Kavanagh.⁹ Relation of growth factors to vitamins has been discussed by Peterson.¹⁰

Yeast metabolism seemed to have something in common with animal metabolism when Meyerhoff in 1918 found the coenzyme of yeast in animal tissue. Bacterial dehydrogenases also received much attention, and a relationship between dehydrogenases and coenzymes became apparent. Respiratory enzymes were under active investigation; in 1932 Warburg and Christian found a combination of the yellow enzyme, a second enzyme prepared from yeast, and a coenzyme prepared from red corpuscles of horse blood which could oxidize hexose-monophosphate. This yellow enzyme contained riboflavin as a prosthetic group. Kuhn and co-workers demonstrated that pure riboflavin stimulated growth of rats maintained on diets low in vitamin B₂. Other riboflavin-containing enzymes have been

isolated, such as d-amino oxidase, xanthine oxidase, and cytochrome reductase. Jansen and Donath¹¹ isolated crystalline thiamine from rice bran. In 1932, Windaus¹² and his colleagues isolated this vitamin from yeast and established its empirical formula. Williams¹³ and co-workers characterized and synthesized thiamine, and the following year Lohmann and Schuster¹⁴ showed that carboxylase from yeast contained a phosphate ester of thiamine, Lwoff and Lwoff¹⁵ observed that the growth factor for *Hemophilus influenzae* and *parainfluenzae* could be replaced by cozymase or Warburg's coenzyme. Niacin (nicotinic acid) was shown to function as a growth factor for *Staphylococcus aureus* by Knight¹⁶ and by Mueller¹⁷ for diphtheria organisms. The anti-black tongue activity of niacin was demonstrated the same year. Existence of pantothenic acid was first suspected by Williams in 1931 in nutritional studies with yeast. Its chemical structure was determined¹⁸ in 1940. The vitamin activity of the substance was clearly established in 1939 by Jukes¹⁹ and Woolley, Waisman, and Elvehjem,²⁰ who showed that it prevented a chick dermatitis which had been recognized since 1930. Biotin was also shown to be identical with vitamin H, which prevented a specific dermatitis caused by continuous ingestion of raw egg white, and the "coenzyme R" of Allison, Hoover, and Burke,²¹ which greatly stimulated growth of *Rhizobium trifolii*. Inositol was isolated from a "bios" concentrate in 1928 by Eastcott,²² but its vitamin activity was not recognized until 1940 when Woolley²³ showed it to cure alopecia in rats. With the advent of the sulfur drugs the anti-sulfanilamide action of p-aminobenzoic acid was revealed and it was soon proved to be an essential metabolite for bacteria and animals. Recently a substance called "folic acid," apparently identical with the "norite eluate factor" for *Lactobacillus casei*, has been isolated but its chemical identity and action in animals has not been reported though it occurs in bacteria, vegetable, and animal tissues. Pfiffner *et al.*²⁴ have suggested that folic acid may be identical with a factor reported by Hogan and Parrott²⁵ called "vitamine B_c" capable of curing severe anemia in chicks. Other growth-stimulating factors have been described, but these have not as yet been identified.

The chemistry of vitamins and their physiological action has been reviewed by Rosenberg²⁶ and Evans *et al.*²⁷ Many other reviews of this subject have been prepared from time to time, notably those appearing in the *Annual Reviews of Biochemistry*.

One of the most important advantages of microbiological assays is the relatively shorter time required for them than for other methods. None of the bacterial methods described in this chapter require more than a three-day incubation period; some yeast methods require only a few hours. Also, the materials and equipment required are relatively inexpensive; generally the usual bacteriological equipment is all that is required. On the other hand, animal experiments require long periods of feeding on a regulated diet free of the vitamin under assay prior to feeding of the assay materials. Chemical methods for members of the B-complex are limited to thiamine, riboflavin, and niacin; for other members, microbiological methods are distinctly advantageous where only small quantities of material are available, for instance, in plant- and animal-tissue experiments.

Microbiological methods share with chemical methods the difficulty involved in preparation of samples prior to assay. Complete extraction of vitamins from their protein complexes without destruction must be accomplished. Animal assays may be performed on unaltered materials, though larger amounts of materials must be stored during the period of assay when vitamin contents may undergo change. Animal experiments must be used to prove biological requirements for a particular compound. Like animal assays, microbiological assays require a basal medium supplying all growth-stimulating agents except the one under assay. In microbiological methods hydrolyzed casein, supplemented by amino acids and along with known vitamins, is often used to supply the nitrogen requirements. These preparations undoubtedly contain many as yet unidentified substances; it is important that these constituents be present in such concentration that only the one missing compound under assay will produce stimulation in growth of the test organism. Microbiological assays of certain natural materials have shown that ordinary methods of preparation of samples prior to assay may not always remove other stimulatory and inhibitory agents; *Lactobacillus casei* may be inhibited or stimulated by small amounts of fatty acids or urea. Hydrolysis of cereal products by strong acids or alkalies produces a compound biologically active for *Lactobacillus arabinosus* and also possessing characteristic reactions of nicotinic acid when determined colorimetrically. Whether this substance is biologically active in animals has not been established.

Specificity of microorganisms for derivatives of vitamins often is in proportion to their activity in animals, though some exceptions to this statement already exist. More information is needed to determine whether these derivatives are present in nature, and if they are, whether the assay organisms used at the present time are capable of being stimulated prop-

erly by them. Otherwise, vitamin potencies determined by microorganisms may not reveal the true biological potency of the material as determined by the higher animals.

A rapidly developing field of study has recently been revealed in the antivitamins. Avidin and the sulfa drugs have been shown to interfere with biotin and p-aminobenzoic acid metabolism respectively. Snell²⁸ reported a sulfonic acid structurally so similar to pantothenic acid that it interferes with pantothenic acid metabolism by organisms requiring the preformed vitamin. Others have been described by Barnett and Robinson.²⁹ It has been suggested that these compounds may result in another class of chemotherapeutic agents similar to the sulfa drugs.

A new application of microbiology in the general field of biochemistry is developing in microbiological determinations of amino acids. While such a discussion is outside the realm of this chapter, it is well to include some of the literature to date. Pollack^{30a} employed a modification of Snell, Eakin, and Williams¹²⁸ yeast growth method for the determination of thiamine for the determinations of β -alanine. More recently Kuiken, Norman, Lyman, and Hale^{30b} have modified the Snell and Wright *Lactobacillus arabinosus* method for the assay of nicotinic acid by supplementing the medium with p-aminobenzoic acid and a tomato concentrate preparation and replacing the casein hydrolyzate with a mixture of amino acids (glutamic acid, tryptophane, threonine, valine, leucine, isoleucine, cystine, lysine, and phenylalanine). The method is particularly suitable for the determination of valine, leucine, and isoleucine. Shankman^{30c} has reported other amino acids necessary for this organism and Shankman, Dunn, and Rubin^{30d} have proposed the assay of eight amino acids including methionine. Horowitz and Beadle^{30e} reported that an X-ray induced mutant of *Neurospora crassa* had lost its ability to synthesize choline, and have reported a microbiological assay based on this observation. Bonner, Tatum, and Beadle^{30f} have announced that another mutant requires supplements of isoleucine and valine. Schenck^{30g} has proposed a microbiological assay for β -alanine employing the diphtheria bacillus.

THIAMINE

This vitamin is known under various names both in the United States and abroad, the most common names being thiamine, aneurin, and vitamin B₁. The pertinent facts about it have been summarized by Waisman.³¹

Thiamine* (vitamin B₁, antiberiberi, antineuritic, antipolyneuritic, C₁₂H₁₇N₄OSCl·HCl, a pyrimidine, thiazolium derivative).

*No uniformity exists in spelling names of vitamins. Some authorities use an e as the last letter while others do not. Consequently both spellings will be found in the literature.

Properties: *Water-soluble.* Destroyed by sustained elevated temperatures. Sensitive to alkali. Destroyed by sulfite. Not readily destroyed by oxidation.

Function: Essential for utilization of carbohydrates as a part of coenzyme, cocarboxylase. Maintains and stimulates appetite and normal intestinal functions. Necessary for normal nerve action. Specific for the deficiency disease, beriberi.

Symptoms Associated With Deficiency: Poor appetite. Digestive disturbances. Irritability. Nervousness. Weakness. Slow heart rate. Cardiovascular upsets. Loss in weight. Multiple neuritis. Edema and muscular atrophy. High blood pyruvic acid.

Daily Requirement: Man, 1.5 to 2.3 mg. Woman, 1.2 to 1.8 mg. Children (1-12 years), 0.4 to 1.2 mg.; (12-20 years), 1.2 to 2.0 mg.

Occurrence in Natural Foodstuffs: Chiefly pork muscle, rolled oats, whole wheat, rye (whole grain), walnuts, green peas, Lima beans, peanuts, milk, corn, beef liver, egg, lean beef, potatoes.

Chemically it is composed of two main parts, commonly called pyrimidine and thiazol, the complete formula being

4-methyl-5- β -hydroxy-ethyl-N-[(2-methyl-4-amino-pyrimidyl-5)]-methyl-thiazolium-chloride-hydrochloride.

Thiamine occurs in all plant and animal tissues, the latter, particularly liver, being excellent sources. Vegetables contain relatively small amounts. Williams and Spies³² discussed the chemistry and physiology of thiamine while Jolliffe³³ considered the clinical aspects of thiamine deficiencies.

Schopfer and Jung's³⁴ Method for Microbiological Assay for Thiamine. This method is based on growth of *Phycomyces blakesleeanus* in an asparagine-mineral salt solution. The basal medium proposed by Schopfer and Jung had the following composition:

Potassium dihydrogen phosphate (KH ₂ PO ₄).....	0.5 gm.
Magnesium sulfate (MgSO ₄ ·7H ₂ O).....	1.5 gm.
Asparagine.....	4.0 gm.
Dextrose.....	100.0 gm.
Distilled water.....	1,000.0 ml.

Bonner and Erickson³⁵ reported that commercial asparagine contained traces of thiamine, removable by recrystallization from water. Cultures are made with 25 ml. of the basal medium in 100-ml. Erlenmeyer flasks. Bonner and Erickson, and Meiklejohn,³⁶ and Sinclair³⁷ modified the procedure by using 10 ml. of medium in 50-ml. Erlenmeyer flasks. Bonner and Erickson added their assay material to the above medium, whereas Meiklejohn and Sinclair used such concentrations of the basal medium and assay material that dilution with water to a total volume of 10 ml. gave a final medium of the above composition. The flasks are sterilized at 15 pounds pressure for 15 minutes, cooled, and inoculated with a spore suspension of *Phycomyces blakesleeanus* prepared from malt agar slants. The number of spores used as an inoculum had no significant effect, over a thousandfold range either in blanks, standards, or assay material.³⁵ Flasks are incubated for 10 days at 20 to 25°C. (68 to 77°F.). At the end of this period the mycelium mat is removed by filtration on previously weighed filter paper or, as preferred by some workers, by a suitable stirring rod. The mycelium mat is dried and weighed. By interpolation from a standard curve, prepared from growth data from a series of standards prepared with each assay series, thiamine contents of the assay material may be computed. Standards are prepared containing 0, 0.05, 0.10, 0.15, 0.20, 0.30, and 0.40 μ g. of thiamine. Bonner and Erickson have shown the standard

curve to be practically linear up to 0.40 μ g. of thiamine per flask. The linearity may be increased somewhat by employing a larger amount of asparagine.³⁵

Leonian and Lilly³⁸ emphasized that major and minor elements should be included in the medium to secure maximum growth of the test organism and eliminate a non-specific stimulation of the organism in the flasks containing assay material. The quantity of glucose and ratio of glucose to amino acids on one hand and thiamine on the other exert marked influence upon growth. Glycine was recommended as a nitrogen source instead of asparagine. Schopfer³⁹ employed glycine while Burkholder and McVeigh⁴⁰ recommended asparagine. The effect of various factors on growth of *Phycomyces blakesleeanus* has been reported by these authors using the following medium:

Glucose.....	40.0 gm.	Fe.....	0.05 mg.
Asparagine.....	4.0 gm.	Zn.....	0.10 mg.
KH ₂ PO ₄	1.5 gm.	Cu.....	0.02 mg.
MgSO ₄ ·7H ₂ O.....	0.5 gm.	Mn.....	0.01 mg.
		B.....	0.01 mg.
Distilled water to 1 liter		Mo.....	0.016 mg.

Boron was supplied as boric acid, molybdenum as molybdate, and the other metals as sulfates. Increasing asparagine from four to eight grams per liter produced only slight increase in dry weight of *Phycomyces* mycelium. As already reported by Schopfer³⁹ little or no growth occurred in the medium having an initial pH below 3 or above 7. Within the range of pH 3.5 to 4.6 the amount of growth was essentially the same. Presence of citrates also enhanced growth, not because of its buffer effect, but probably because it served as an auxiliary carbon source since a phosphate buffer had no effect.

Temperature of incubation plays an even more important role. Maximum mycelium yields occur at 15°C.(59°F.) but fall off rapidly below and above this temperature, more so at lower thiamine levels. Decrease in yields is less marked at high thiamine levels. The lower yields recorded above 15°C. were not due to autolysis; only 10 per cent loss in weight of mycelium occurred in 19 days at 25°C.

The amount of surface area also influenced yields of mycelium; nearly maximum yields were obtained where the surface area of the medium was 100 to 150 sq. cm. Thus, any considerable difference in size of culture vessels in comparable experiments will introduce an important variable. Burkholder and McVeigh⁴⁰ used the *Phycomyces blakesleeanus* method in studies of thiamine contents of green plants, using 25 ml. of medium in 125-ml. Erlenmeyer flasks incubated 10 days at 20°C.(68°F.) after which the fungus mats were dried and weighed. With maize-leaf tissue, thiamine values per gram of material were practically constant through the range of 0.1 to 0.4 gram per flask but were considerably higher outside this range. With a number of different plants, samples of about 100 mg. gave minimum values. It may be necessary to determine these points by preliminary experiments. The possibility exists that inhibiting or stimulating agents may be added with the assay material, though Bonner and Greene⁴¹ have reported satisfactory agreement between direct *Phycomyces* assays and thiamine determinations by a thiachrome method. The "Z factor" of Robbins and Hamner⁴² may be involved.

Henry, Riker, and Duggar^{24a} have demonstrated that glucose concentrations of five and ten per cent produced essentially the same assay values. Glycine, aspartic acid and asparagine were each demonstrated to be suitable nitrogen sources. Employing glycine and asparagine as nitrogen sources, thiamine values were almost identical; aspartic acid gave an average value slightly higher. Glycine was preferred because of its purity and relatively low cost. It was used in a concentration of 2.27 grams per

liter. Incubation periods of seven days were preferred. Considerable increase in mycelium weights were noted between the fifth and sixth days; the difference between assay results determined at seven and eight days were negligible. The medium employed by Henry *et al.* was prepared double strength with magnesium sulfate, 0.5 gm.; potassium dihydrogen phosphate, 1.5 gm.; zinc, 0.2 p.p.m.; iron, 0.2 p.p.m.; manganese, 0.02 p.p.m.; glucose, 100 gm.; glycine, 4.54 gr., and distilled water to make 500 ml. The pH was adjusted to 5.5 with sodium hydroxide. To 50 ml. of this medium was added thiamine solution or tissue extract and the volume then brought to 100 ml. with distilled water. Twenty-five-milliliter portions of this solution were added to each of four 250-ml. Erlenmeyer flasks, giving a quadruplicate series for each concentration. The check series included concentrations of crystalline thiamine from 0 to 0.3 micrograms per 25 ml. of medium.

Hamner *et al.*^{42b} have discussed the *Phycomyces* assay as adapted to the routine assay for thiamine in a large number of materials. Good results were obtained in comparing the results with those obtained by the rat-curative and thiochrome methods, when applied to vegetable materials. It gives consistent results on wheat. On meats, the fungus method gave consistently higher results.

Phycomyces blakesleeanus, besides utilizing the thiamine molecule, will grow equally well in a mixture of the thiazole and pyrimidine which were the two fractions used by Williams and Kline⁴³ in synthesizing the molecule. Robbins and Kavanagh⁴⁴ showed that in mixtures of thiazole and pyrimidine these two components of the vitamin molecule are utilized in equimolecular amounts. Bonner and Erickson showed that the growth resulting is equivalent to that of equimolar thiamine. Thiochrome is inactive. However, the organism will not grow in the presence of either fraction of the molecule alone. This fact makes it possible to directly assay either the pyrimidine or thiazole content of biological materials. Rats are unable to utilize mixtures of the two fractions in place of the vitamin molecule.

The effect of several analogues of pyrimidine, thiazole, and thiamine were studied by Robbins and Kavanagh.⁴⁵ Much variation existed as to the thiamine requirements of fungi and their ability to utilize either or both of the fraction of the thiamine molecule. Such a grouping was first proposed by Robbins⁴⁶ and has been expanded by Robbins and Kavanagh.⁹ This suggests another method of assaying for thiamine or its components.

The *Phycomyces blakesleeanus* assay of thiamine in blood was applied by Meikeljohn.⁴⁷ His method was criticized by Sinclair⁴⁸ on the basis that the nitrogen sources as well as other factors in blood were affecting the

apparent thiamine values. Lehmann and Nielson⁴⁹ reported the medium should be maintained between pH 5.7 and 6.8 and that asparagine concentration could be varied between 0.2 and 0.4 per cent without affecting the growth so long as the quantity of thiamine did not exceed 0.4 μ g.

Increase in rate of alcoholic fermentation, as measured by carbon dioxide evolution, by *Saccharomyces cerevisiae* on the addition of thiamine chloride was first recognized by Schultz, Atkin, and Frey⁵⁰ as a method for quantitative determination of this vitamin. Theirs was one of the first microbiological assay methods to be successfully employed. The complete method as first used was published in 1937. The yeast fermentation method for thiamine assay has been modified slightly by Josephson and Harris⁵¹ so that microdeterminations of this vitamin may be made in Summerson-Warburg equipment.⁵² The only interfering substance of any significance thus far found is 2-methyl-5-ethoxymethyl-6-amino pyrimidine.⁵⁰ The corresponding 5-hydroxymethyl compound is a hydrolysis product of thiamine and also is an active stimulant. Except for its possible existence in urine, it has not been found to any great extent in nature.

The method as first described employed no correction for stimulation by substances other than thiamine. Nicotinic acid was soon found to interfere with the assays of certain substances and this compound was then added to the basal medium.⁵³ Adenylic acid was inactive. When the direct-assay method was applied to urine numerous interfering compounds, notably the pyrimidine portion of the thiamine molecule, were encountered. Consequently an indirect assay was employed in which thiamine was assayed by difference between the total stimulation recorded and that given by an equivalent amount of urine freed of thiamine. Thiochrome, an oxidation product of thiamine is biologically inactive. Alkaline ferricyanide under controlled conditions may be used to oxidize thiamine to thiochrome and this procedure was adopted.⁵⁴ This procedure was not very satisfactory because the efficiency of the oxidation varied from time to time. More recently, Schultz, Atkin, Frey, and Williams⁵⁵ have shown that sodium sulfite may be used to destroy thiamine by cleavage of the molecule forming 2-methyl-6-aminopyrimidine-5-methyl sulfonic acid and 4-methyl-5-(β -hydroxy)-ethyl thiazole, both of which are inactive toward yeast. Cocarboxylase, (diphosphothiamine) is also inactive, while the above-mentioned interfering pyrimidine is unaffected. Thus, as the method has been more recently revised⁵⁶ "the thiamine content of an unknown substance is equivalent to that portion of the fermentation activity of the substance which can be destroyed by treatment with sulfite." The method described here is that reported in 1942 and employs one-half

the quantities of reagents and assay materials employed in the original method. Also, a new type fermentometer is described.

Schultz, Atkin, and Frey's⁵⁶ Fermentation Method for Assaying for Thiamine With *Saccharomyces cerevisiae*. Two preparations are made of each substance to be analyzed—one treated with sulfite and one untreated—then fermentation activities are determined with the aid of a fermentometer. The difference, expressed in terms of pure thiamine chloride, is taken as a measure of the thiamine content of the unknown.

Preparation of Samples: A water-soluble substance is dissolved in a convenient volume of water (depending upon the potency of the sample). Insoluble materials must be finely divided either in the dry state by grinding or in the wet state by means of the Waring Blendor or its equivalent. The latter procedure has been found particularly useful in the preparation of bread and tissue samples. The suspension should be dispersed well enough to permit the measurement of an accurate aliquot by means of a pipette. The solution or suspension is made acid to Congo red paper with sulfuric acid and heated to 100°C. (212°F.) for 20 minutes. This is conveniently done in an Arnold steam sterilizer. When cool the solution is made to volume and a portion is taken for sulfite treatment (described below). The remainder is neutralized to neutral litmus paper by means of sodium hydroxide and is then used for the determination of total fermentation activity—i.e., before sulfite treatment.

Treatment With Sulfite: In a 50-ml. Pyrex Erlenmeyer flask is placed an aliquot (not exceeding 20 ml. in volume) of the samples prepared as above, and 0.7 ml. of N sulfuric acid and 5 ml. of a freshly prepared solution of sodium sulfite, containing 0.2 gram of the salt per 5 ml., are added. The reaction is adjusted to pH 5.2 to 5.6 with dilute sulfuric acid or sodium hydroxide solutions using bromocresol purple as an outside indicator to set the pH. The flask is capped with a 30-ml. beaker, heated to 100°C. for 30 minutes, and then cooled. Excess sulfite is destroyed by the addition of the exact quantity of a three-per cent solution of hydrogen peroxide. The end point of the reaction is determined with the aid of an outside indicator made by mixing one drop of five-per cent potassium iodide, one drop of one-per cent soluble starch indicator, and one drop of 50-per cent sulfuric acid. This mixture develops a pink tinge which gets darker with time. If a drop of a sulfite-containing solution is transferred to this indicator by means of a glass rod, the pink color is discharged. As the end point of the titration is approached the pink color fails to disappear, and when an excess of peroxide is present a deep violet color appears.

When the excess sulfite has been destroyed the solution is neutralized to neutral litmus with sodium hydroxide and made to volume, and an aliquot portion is used for the determination of residual fermentation activity.

REAGENTS FOR THE FERMENTATION ACTIVITY

All chemicals used should be the best grade commercially available.

Solution A: One liter contains 180 grams of ammonium dihydrogen phosphate, 72 grams of diammonium hydrogen phosphate, and 0.2 gram of nicotinic acid. This solution should be sterilized by heating at 100°C. (Arnold sterilizer) for 30 minutes. If desired, the sterile buffer solution may be transferred to a sterile automatic buret and thereafter kept at room temperature. If such a buret is not available the solution may be handled in the same manner as Solution B.

Solution B: One liter contains 200 grams of glucose (anhydrous), 7 grams of magnesium sulfate ($\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$), 2.2 grams of potassium dihydrogen phosphate, 1.7 grams of potassium chloride, 0.5 gram of calcium chloride ($\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$), 0.01 gram of ferric chloride ($\text{FeCl}_3 \cdot 6\text{H}_2\text{O}$), and 0.01 gram of manganese sulfate ($\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$). Solution B should be distributed in 500-ml. Erlenmeyer flasks, cotton-plugged, and sterilized at 100°C. on three successive days. Thereafter the flasks should be capped with foil or paper and then may be stored at room temperature. After a flask has been opened (for use) it is kept in a refrigerator at 4°C. until empty.

Thiamine Standard Solution: A quantity of crystalline thiamine chloride is dried over phosphorous pentoxide for 24 hours. A weighed amount is dissolved in distilled water to make a solution containing 0.1 mg. of thiamine chloride per milliliter. A sub-

dilution is made to contain 1 μ g. per milliliter. This solution is distributed in 200-ml. Erlenmeyer flasks (cotton-plugged), sterilized at 100°C. for 20 minutes on two successive days, and then treated like Solution B.

Yeast Suspension: Fleischmann bakers' yeast (10 grams) or its equivalent is weighed into a deep weighing scoop or a small beaker. The small foil-wrapped cakes of yeast or the high-vitamin B₁ bakers' yeast should not be used. Distilled water is added to the yeast, slowly at first, until a smooth, heavy cream has been produced, and then enough is added to make the volume of the suspension to 200 ml. This suspension is made just prior to each run.

Fermentometer: The fermentometer consists of a water thermostat maintained at $30 \pm 0.2^\circ\text{C}$., a shaking device, and a series of gasometers. The new fermentometer described by Schultz, Atkin, and Frey⁵⁶ is based on a parallelogram. Two racks, each holding six reaction bottles in clips of spring-tempered bronze, are placed along the long side of the parallelogram. The inside corners of these racks are joined by hinges to two small plates which are supported by hinges in such a manner that they may pivot. By proper adjustment of the hinges all bottles may receive a uniform shaking motion. An eccentric drive is applied at a rate of about 96 r.p.m.

The reaction bottles are connected by rubber tubing to gasometers, six on each side mounted on detachable boards. The gasometers consist of 260-ml. graduated cylinders (graduations at each two ml.) which are drawn together sufficiently at each end to attach rubber tubing. The upper end is connected to the reaction bottle and the lower end to a leveling bulb. Each contains 10 per cent calcium chloride colored blue with cupric chloride.

In conducting the assay, 2.5 ml. of Solution A and 7.5 ml. of Solution B are dispensed into each reaction bottle, followed by addition of the thiamine-containing solution under assay. In reaction bottles No. 1 and No. 2 are placed one microgram and two micrograms, respectively, of thiamine solution. In reaction bottle No. 3 is placed an aliquot of the test sample, containing between one and two micrograms of thiamine. In reaction bottle No. 4 is placed an aliquot of the same sample of the sulfite treatment. If the fermentation activity of a large aliquot of the unknown or the sulfite-treated unknown is still below one microgram, one may add one microgram of thiamine to the unknown and thus bring it into the proper range. Distilled water is then added to each reaction bottle to make the volume to 40 ml. Noting the time, 10 ml. of the yeast suspension containing 0.5 gram of moist compressed yeast is added to each bottle as rapidly as possible. A free flowing pipette is desirable for this operation.

With a minimum of wasted time all the reaction bottles are placed in the fermentometer and connected to the gasometers. Shaking is started and after two to three minutes the initial reading of the gas volumes is made. At the end of three hours from the time of adding the yeast suspension, the final reading of the gas volume is made. The difference represents the gas evolved.

The fermentation activities of the treated and untreated samples are calculated in terms of micrograms of thiamine per gram of sample, and the difference between these values represents the true thiamine content.

The apparatus and technic may be considered satisfactory when duplicate fermentation measurements, made simultaneously, differ by less than two per cent. Uniform temperature, uniform shaking, freedom from leaks, and accurately calibrated gasometers are necessary if this criterion is to be met. When making these preliminary tests it is also desirable to check the rate of shaking, making certain that the rate is not so slow that the yeast settles out of suspension, thereby causing a supersaturation of carbon dioxide and consequent irregular gas evolution. On the other hand, the shaking rate should not be so fast that the reaction mixture is violently thrown against the stopper.

The difference in the three-hour gas total between one and two μ g. of thiamine should not be less than 20 ml. and preferably closer to 30 ml. If the increase in fermentation rate is satisfactory, the apparatus and solutions are ready for use. The fermentation activity of an unknown is established on the basis of linearity of response between the stimulation produced by one and two μ g. of thiamine. If the fermentation activity of a large aliquot of the unknown is still below one μ g., as frequently happens

after sulfite treatment, one may add one $\mu\text{g.}$ of thiamine to the unknown and thus bring it into the proper range.

Where routine thiamine assays are made on the same material prepared according to an unchanging process and formula, Laemmle and Barlow ⁵⁷ have shown that a calculated sulfite blank may be used. Comparison of assays made by the thiochrome method and the fermentation method with sulfite blank and calculated blank was applied to enriched bread. Closer agreement between the two methods was obtained when the calculated blank was applied.

Knott, Kleigler, and Torres-Bracamonte ⁵⁸ applied the fermentation technic to the determination of pyrimidine and thiamine in milk, as have Gorham, Abels, Robins, and Rhoades ⁵⁹ to the determination of these two substances in blood cells and urine. Bunzell ⁶⁰ has adapted the yeast fermentation method to micro-determinations of thiamine through the use of enzyme reaction vessels to which a manometer is attached, graduated so that each division is equivalent to 100 $\mu\text{g.}$ carbon dioxide. A simpler vessel of similar design was described earlier.

Williams, McMahan, and Eakin's ⁶¹ Method for Assaying for Thiamine With *Saccharomyces cerevisiae*. Williams, McMahan, and Eakin developed a satisfactory thiamine assay based on growth response of *Saccharomyces cerevisiae*. The two strains used were American Type Culture Collection No. 578 and the "Old Process" strain of the Fleischmann Company. The basal medium consists of the following reagents:

Sucrose.....	20.0 gm.
KH ₂ PO ₄	2.0 gm.
(NH ₄) ₂ SO ₄	3.0 gm.
l-asparagine.....	0.75 gm.
CaCl ₂	0.25 gm.
MgSO ₄ ·7H ₂ O.....	0.25 gm.
H ₃ BO ₃ , ZnSO ₄ , MnCl ₂ , TiCl ₃	1.0 mg. each
FeCl ₃	0.5 mg.
CuSO ₄ ·5H ₂ O.....	0.1 mg.
KI.....	0.1 mg.
Inositol.....	5.0 mg.
Biotin.....	0.2 $\mu\text{g.}$
Calcium pantothenate.....	300.0 $\mu\text{g.}$
Pyridoxine hydrochloride.....	20.0 $\mu\text{g.}$
Folic acid.....	0.5 $\mu\text{g.}$
Vitamin-free hydrolyzed casein.....	0.4 gm.*
Distilled water to make 1 liter	

* This amount of hydrolyzed casein is double the amount recommended in the original description of this method. (Univ. of Texas Pub. 4237, p. 11 (1942)).

The pH of the basal medium is approximately 4.7. If it is more acid than pH 4.3 the yeast fails to grow satisfactorily.

Buffer Solution for Thiamine Assay:

Acetic acid, glacial.....	3.75 gm.
Sodium acetate, anhydrous.....	5.00 gm.
Distilled water to make 1 liter	

57. Laemmle and Barlow. 1942. Cereal Chem. 19, 540-546.
58. Knott, Kleigler, and Torres-Bracamonte. 1943. J. Nutr. 25, 49-58.
59. Gorham *et al.* 1942. J. Clin. Invest. 21, 161.
60. Bunzell. 1917. J. Biol. Chem. 17, 409-411; Ind. Eng. Chem., Anal. Ed. 14, 279-280;
61. Williams, McMahan, and Eakin. 1941. Univ. of Texas, Pub. 4137, 34-35.

In this buffer solution (pH 4.7) all thiamine solutions may be heated without danger of destruction. This is approximately the pH of the basal medium and permits good growth of the yeast.

Buffer Solution Containing Thiamine-Free Liver and Yeast Extract:

Thiamine-free liver extract (25 mg./ml.).....	5 ml.
Thiamine-free yeast extract (25 mg./ml.).....	5 ml.
Buffer solution to make.....	50 ml.

Thiamine-Free Liver and Yeast Extracts: Five grams of liver paste (Wilson's Laboratories 1-20) are added to 195 ml. of water, autoclaved for 15 minutes, and cooled to room temperature. The pH is adjusted to approximately 3. Ten grams of Fuller's earth are added, the mixture is shaken for 30 minutes, filtered, and the pH is adjusted to approximately 1. After autoclaving again for 15 minutes and cooling, a second 10-gram portion of Fuller's earth is added and the mixture is shaken for at least two days. At the end of this time it is filtered, the pH is adjusted to 4.5 to 4.8, and filtered again. The filtrate is divided into five-ml. portions, placed in plugged test tubes, autoclaved 15 minutes, and stored in the refrigerator until ready for use.

The same procedure is followed for Difco yeast extract.

Method of Assay: Assays are carried out in ordinary bacteriological test tubes, supported in a convenient rack which may be autoclaved.

A set of standard thiamine levels is set up with each assay series, corresponding to 0, 0.0002, 0.0004, 0.0006, 0.0008, 0.0012, and 0.0020 μ g. of thiamine. Owing to the instability of thiamine, all standard solutions are prepared in the buffer solution described above.

Various amounts of tissue extracts to be assayed are diluted with buffer by preliminary experiment or estimate so as to contain from 0.0001 to 0.0012 μ g. of thiamine. Volumes up to .1 ml. may be used. All samples are pipetted by the use of syringe-type micropipettes, after which 0.4 ml. of buffer solution containing thiamine-free liver extract and thiamine-free yeast extract are added to each tube.

Enough basal medium to supply two ml. per tube for all the tubes in the test is put into one flask, and another 10 to 15 ml. portion of medium is put into a smaller flask to be used in seeding. The medium, racks of tubes, a 10-ml. and a one-ml. graduated pipet are steamed for 10 minutes and then cooled to room temperature. The small flask of medium is inoculated from an agar slant of the organism. The yeast is suspended uniformly and the number of milligrams of moist yeast cells per milliliter of solution is determined by use of a suitable photoelectric colorimeter and the appropriate calibration curve. By calculation, enough of this suspension is taken to inoculate the large amount of medium with 0.08 mg. of moist yeast per 100 ml. of medium. After introduction of the yeast suspension and thorough shaking, two ml. of the medium are added to each tube in the test. The tubes are shaken thoroughly and placed in a 30°C. (86°F.) water bath for a growth period of approximately 15 hours.

The turbidity produced in the various tubes after 15 hours' incubation may be quantitatively determined in a photoelectric colorimeter or thermoelectric turbidimeter. When the tubes are removed from the incubator, they are placed in the refrigerator for 10 minutes to retard the rate of growth of the organism. They are then diluted with five ml. of a saturated solution of chlorothymol. The tubes are then shaken vigorously, allowed to stand for a few moments to discharge air bubbles, suspended again by less vigorous shaking, and then read in the turbidimeter.

Extensive direct comparisons of thiamine values in identical extracts by this and other methods were not reported. However, recovery of thiamine added to various animal tissues showed satisfactory recovery. Autolysis for 24 hours was relied upon to convert the cocarboxylase of the tissue into a form assimilable by the yeast.

The thiazole and pyrimidine fractions of the thiamine molecule are both active under the conditions used in this test. Comparative assays with thiamine show that on an equimolecular basis the pyrimidine portion has approximately 30 per cent and the thiazole portion approximately 70 per cent of the activity of pure thiamine chloride.

Treatment of thiamine with sodium sulfite under the conditions described by Schultz, Atkin, Frey, and Williams⁵⁵ results in destruction of approximately 70 per cent of the activity of the vitamin. Cocarboxylase, the phosphoric acid ester of thiamine, is practically inactive as a growth stimulant in this test. It may be converted to thiamine by enzyme action, thus it may be possible to differentiate between the amounts of cocarboxylase and free thiamine in tissue.

Silverman and Werkman's⁶² Fermentation Method for Assaying for Thiamine With *Propionibacterium pentosaceum*. They showed that the addition of thiamine to cells of *Propionibacterium pentosaceum* in a medium free of the vitamin resulted in an almost immediate increase in their anaerobic pyruvate metabolism as judged by the evolution of carbon dioxide. The assay is based on the above observation.

The stock culture of *Propionibacterium pentosaceum* was grown on a medium consisting of 1 per cent glucose, 0.3 per cent yeast extract (Bacto), and 0.2 per cent peptone (Bacto). It was transferred daily, four drops of inoculum being transferred to 25 ml. of the above medium, and incubated at 30°C.(86°F.).

The basal medium employed in the assay consisted of the following:

Glucose.....	1.0	per cent
Sodium acetate.....	0.6	per cent
Ammonium sulfate.....	0.3	per cent
Cystine.....	0.005	per cent
Hydrolyzed casein.....	0.075	per cent
Ether extract of three grams yeast extract per 100 ml. Speakman's salts in half concentration		

Three hundred ml. of the above medium were placed in 500-ml. flasks and also in 25-ml. and five-ml. portions.

In preparation for a thiamine assay the actively growing cells of *Propionibacterium pentosaceum* from 25 ml. of the yeast extract-peptone medium were aseptically recovered by centrifugation, washed twice with two 10-ml. portions of sterile distilled water, and resuspended in five ml. of sterile water. One drop of this suspension was used to inoculate a five-ml. portion of the basal medium. This culture was incubated 24 hours at 30°C., centrifuged, the cells washed with 10 ml. of sterile water, resuspended in five ml., and the entire contents used to inoculate a 25-ml. portion of the basal medium. This in turn was incubated for 24 hours at 30°C. and, after washing in 10 ml. of sterile water, was employed as an inoculum for 300 ml. of the basal medium. The contents of the flask were incubated for 72 hours at 30°C., the cells obtained were washed twice in distilled water, and then employed as test organisms for a manometric assay for thiamine. The second washing was carried out in a 12-ml. graduated centrifuge cup and the volume of cell paste was recorded after 20 minutes centrifuging at about 1,900 r.p.m.

The cell paste obtained from a single flask of medium was made up to 12 ml. with M/15 phosphate (pH 5.6) and one ml. of this suspension was placed in the main vessel of each Warburg cup. Nine mg. of pyruvic acid as sodium pyruvate were employed as a substrate and placed in the side arm. Varying amounts of thiamine contained in a volume of 0.1 ml. of water were added to the cells in the main vessel. After shaking in the water bath at 30°C. for 30 minutes, the contents of the side cup were tipped into the main vessel and readings taken. The atmosphere was nitrogen from which all oxygen had been removed by passage over hot copper. Total volume contained in the cups was in all cases 2.3 ml. Simple Warburg manometers are employed and details of manometric technic are described by Dixon.⁶³

Carbon dioxide measurements are made at the end of 2.5 hours and are corrected for endogenous carbon dioxide production. The method may be used to assay for thia-

62. Silverman and Werkman. 1938. Soc. Expt. Biol. and Med. Proc. 38, 823-827; J. Bact. 38 (1939), 25-32.

63. Dixon. 1934. Manometric Methods, Cambridge Univ. Press.

mine in concentrations of 0.002 to 0.25 μg . Fairly accurate approximations of thiamine may be obtained if extracts are tested in several dilutions with their vitamin contents within the range of the test described.

The manometric determination is not affected by the presence of the pyrimidine or thiazole fraction of thiamine nor by nicotinic acid in the amounts tested (up to 10 μg .).

Silverman and Werkman reported satisfactory assays on 0.025 to 0.05 gram of dried bacterial cells but on no other materials.

One difficulty with this method lies in the fact that *Propionibacterium pentosaceum* is able to become adapted to the synthesis of thiamine on serial transfer in a medium free from the vitamin.

Niven and Smiley's Method for Assaying for Thiamine With *Streptococcus salivarius* as the Test Organism. Stock cultures are maintained as stab cultures in a meat infusion agar plus one per cent tryptone, 0.1 per cent glucose, 0.2 per cent K_2HPO_4 , 1.5 per cent agar and an excess of CaCO_3 . The thiamine-free basal medium, as finally diluted, contains the following:

Casein hydrolyzate.....	0.5 gm.
Thiamine-free yeast extract.....	0.3 gm.
Glucose.....	1.0 gm.
Phosphate buffer (0.4 M, pH 7.4).....	10.0 ml.
Salt solution.....	1.0 ml.
Sodium thioglycolate.....	10.0 mg.
Uracil.....	0.5 mg.
Nicotinic acid.....	50.0 μg .
Riboflavin.....	50.0 μg .
Calcium pantothenate.....	50.0 μg .
Biotin (methyl ester).....	0.1 μg .
Distilled water to.....	100.0 ml.

Hydrolyzed Casein: A 10 per cent acid-hydrolyzed vitamin-free casein solution is prepared in the usual manner with the use of sulfuric acid and subsequent removal of the acid with barium hydroxide. Traces of thiamine, if present, are removed with norite (20 gm. per 100 gm. casein) at pH 3.0. Since the test organism is able to synthesize tryptophane, it is unnecessary to replenish the hydrolyzate with this amino acid.

Thiamine-Free Yeast Extract: Six grams of Difco yeast extract are dissolved in 200 ml. of water and autoclaved for 15 minutes. The pH is adjusted to 3, 10 gm. of Fuller's earth are added, the mixture is shaken for 30 minutes. After filtering, the filtrate is adjusted to pH 1 and autoclaved another 15 minutes. On cooling, a second 10-gm. portion of Fuller's earth is added and the mixture is shaken mechanically overnight. After filtering, 1.5 gm. of K_2HPO_4 are added to the filtrate, which is then adjusted to pH 7.4 and autoclaved another 15 minutes. The resulting precipitate is filtered out and the volume adjusted to 200 ml. and the preparation sterilized in convenient amounts. The added phosphate serves a twofold purpose of destroying the remaining traces of thiamine and removing substances which would precipitate in the complete medium.

Other Medium Constituents: A stock solution of phosphate buffer is made by mixing equal volumes of 0.4 M K_2HPO_4 and KH_2PO_4 and adjusting to pH 7.4.

Stock solution of salts consists of 10 gm. of NaCl , 0.8 gm. of MgSO_4 , 40 mg. of ferrous sulfate ($\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$) and 12 mg. of manganese chloride in 100 ml. of distilled water.

The assay is conducted in standard bacteriological test tubes which have been selected to be free from scratches and are of constant diameter. The above medium is prepared double strength, and five-ml. aliquots dispensed in each tube. Distilled water is added in such quantities that the final volume will be 10 ml. after addition of the test solution. Thiamine is destroyed on autoclaving in neutral or alkaline solutions,

so it must be added aseptically after sterilization of the basal medium. Volumes of the test solution up to five ml., estimated to contain between 0.1 and 0.6 millimicrogram of thiamine, may be used.

Inocula are prepared in the above medium containing 10 millimicrograms of thiamine per 10 ml.; 0.5 ml. of this culture is mixed with 10 ml. of sterile saline solution and one drop of this suspension is employed as inoculum for the assay tubes. Inocula may be subsequently prepared by repeated subculture on the basal medium supplemented with thiamine.

A standard curve is constructed from turbidity measurements of tubes of the basal medium supplemented with thiamine, in the range of 0.1 to 2.0 millimicrograms of thiamine per 10 ml. of medium.

The test organism does not respond to the thiazole or pyrimidine fractions of the vitamin, either alone or in combination. Sulfite cleavage of pure thiamine solutions indicated complete destruction of the vitamin. Cocarboxylase is approximately 40 per cent more active than thiamine on an equimolecular basis. Takadiastase treatment of cocarboxylase solutions lowered the activity of the solution to the normal value.

Gaines and Stahly⁶⁴ have suggested that *Leuconostoc mesenteroides* may be used for assaying for thiamine, nicotinic acid, pyridoxin, pantothenic acid, and biotin in a medium consisting of acid-hydrolyzed casein, cystine, tryptophane, glucose, and inorganic salts. This method would have distinct advantages over the yeast methods in that growth responses could be determined by turbidity measurements or by titration of the acid produced during growth, thus making the method similar to many of the bacterial methods for other members of the vitamin-B complex.

RIBOFLAVIN

The known functions of riboflavin lie in the flavin-containing enzymes associated with carbohydrate and purine metabolism. In this group of enzymes the prosthetic groups may be either of two forms, riboflavin mononucleotide or dinucleotide. The biologically active flavin is a derivative of isoalloxazine with two methyl groups and a pentose sugar, d-ribose. Prior to isolation of the pentose sugar it was called "lactoflavin," "ovoflavin," or "heptaflavin." The properties of the vitamin have been summarized by Waisman.³¹

Riboflavin (vitamin G, lactoflavin, ovoflavin, $C_{17}H_{20}N_4O_6$, ribose alloxazine derivative).

Properties: Water-soluble, greenish fluorescent pigment. Stable to heat. Deteriorates on exposure to light. Rapid destruction in alkali and exposure to light.

Function: Component of flavoproteins which act as important enzymes in tissue respiration. Prevents abnormal eye changes which result in dimming of vision. Necessary for maintenance of normal nerve structure. Necessary for normal growth.

Symptoms Associated With Deficiency: Impaired growth. Lack of vigor. Impairment of tissue respiration. Weakness. Loss of body weight. Glossitis. Cheilosis (fissures at corner of mouth). Neuritis. Vascularizing keratitis. Cataract.

Daily Requirement: Man, 2.2 to 3.3 mg. Woman, 1.8 to 2.7 mg. Children (1-12 years), 0.6 to 1.8 mg.; (12-20 years), 1.8 to 3.0 mg.

Occurrence in Natural Foodstuffs: Chiefly beef liver, milk, eggs, lean beef, pork muscle, whole wheat, oats.

In animals riboflavin deficiency is manifest by retardation and later by complete cessation of growth. In rats the skin and eyes are involved, and in advanced cases the eyelids are often stuck together with serous, reddish fluid. Unless treated, death usually follows. General lack of vigor

64. Gaines and Stahly, 1943. J. Bact. 45, 441-449.

and pediculosis are associated with chronic deficiencies. In chicks, riboflavin deficiencies produce a so-called "curled-toe paralysis." Egg production and hatchability are influenced. Sudden fatal collapse is a syndrome in dogs and pigs. The role of riboflavin in nutrition has been discussed by György.⁶⁵

Snell and Strong's⁶⁶ Method for Assaying for Riboflavin. This widely used assay method for riboflavin is based on the proportional response of *Lactobacillus casei* ϵ (Amer. Type Culture Collection, No. 7469) to varying amounts of riboflavin. Kemmerer⁶⁷ recommended tentative adoption of the method by the Association of Official Agricultural Chemists for determination of riboflavin in yeast, dried skim milk, alfalfa meal, whole-wheat and white flour. A similar procedure, using the same organism, has been developed by Landy and Dicken.⁶⁸ It is given later in this chapter. The organism used by Snell and Strong is believed to be identical with *Bacillus casei* ϵ of Freudenreich and Thoni.⁶⁹ Its actual identity may be doubtful. Some have called it *Lactobacillus helveticus*. Tittsler, Rogosa, and Whittier,⁷⁰ however, have shown that the particular strain used in the assays is more closely related to *Lactobacillus casei* than to *Lactobacillus helveticus* from its growth conditions and the fact that it forms d-lactic acid. Also it may be pointed out that true strains of *Lactobacillus casei* give maximum growth in the basal medium in the absence of riboflavin, whereas members of the *Lactobacillus helveticus-bulgaricus-acidophilus-lactic* group fail to grow in the medium regardless of the presence of riboflavin.

Specificity of the Test Organism: Ability of certain synthetic flavins to supplant riboflavin was investigated by Snell and Strong.⁷¹ The 13 flavins studied were classified as follows:

- I. Those supporting growth as the sole source of flavin on repeated subcultures:
 - 6,7-dimethyl-9-(d,1'-ribityl)-isoalloxazine (riboflavin)
 - 6-methyl-9-(d,1'-ribityl)-isoalloxazine
 - 7-methyl-9-(d,1'-ribityl)-isoalloxazine
 - 6-ethyl-7-methyl-9-(d,1'-ribityl)-isoalloxazine
- II. Those possessing detectable activity only in the presence of suboptimal amounts of riboflavin:
 - 6,7-dimethyl-9-(d,1'-arabityl)-isoalloxazine
 - 6,7-dimethyl-9-(l,1'-arabityl)-isoalloxazine
 - 5-ethyl-7-methyl-9-(l,1'-arabityl)-isoalloxazine
 - 5,6-benzo-9-(d,1'-ribityl)-isoalloxazine
- III. Those possessing no detectable activity under any of the test conditions tried:
 - 6,7-dimethyl-9-(l,1'-sorbityl)-isoalloxazine
 - 9-(l,1'-arabityl)-isoalloxazine
 - 6,7,9-trimethyl-isoalloxazine (lumiflavin)
 - 6,7-dimethyl-alloxazine (lumichrome)
 - riboflavin tetraacetate

Of the flavins listed in Group I, only the last approached the activity of riboflavin. A comparison of the biological activity of the above flavins in rats showed a very close correlation with the activity for *Lactobacillus casei* ϵ . The test organism is also able to grow well where the basal medium is supplemented with certain combined forms of riboflavin. Feeney and Strong⁷² obtained successful assays of Warburg's flavin-adenine-dinucleotide and two samples of milk flavo-protein. However, addition of relatively

large amounts of pyridoxine, pantothenic acid, nicotinic acid, factor W, biotin, coenzyme, and adenylic acid to the basal medium had no significant effect on the assay of pure riboflavin. Amino acid requirements of this organism have been discussed by Hutchings and Peterson.⁷³

The basal medium, the concentration of which is twice the desired final concentration, is composed of the following constituents:

Photolyzed sodium hydroxide treated peptone.....	10 gm.
(plus sodium acetate)	
Cystine hydrochloride.....	200 mg.
Yeast supplement.....	2 gm.
Glucose.....	20 gm.
Inorganic salts—Solutions A and B.....	5 ml. each
Distilled water to one liter; pH adjusted to 6.6-6.8.	

The constituents of the medium are prepared as follows:

Photolyzed Sodium Hydroxide-Treated Peptone: A mixture of 40 grams of peptone (Difco) in 250 ml. of water and 20 grams of sodium hydroxide in 250 ml. of water is exposed in a 25-cm. crystallizing dish to light from a 100-watt bulb with reflector at a distance of approximately 20 cm. for six to 10 hours, and is then allowed to stand at room temperature for an additional 18 to 14 hours (24 hours in all). The sodium hydroxide is neutralized with glacial acetic acid (27.9 ml.), seven grams of anhydrous sodium acetate are added, and the mixture is diluted to 800 ml. This solution contains an equivalent of five per cent of peptone and six per cent of sodium acetate, which is ten times the concentration of these materials in the final medium. It is preserved under toluene. The above treatment destroys other substances⁷⁴ which are essential for growth. These are supplied in the yeast supplement.

Riboflavin in the above solution may be removed completely if the alkaline solution is placed in a large Erlenmeyer flask and is allowed to stand in direct sunlight for 24 hours. The Texas investigators recommend incubation at 37°C., for 24 hours.

Yeast Supplement: To a solution of 100 grams of Bacto yeast extract in 500 ml. of water, 150 grams of basic lead acetate (Horne's sugar reagent) suspended in 500 ml. of water are added, and the precipitate is filtered off. Ammonium hydroxide is added to a pH of about 10, and the precipitate formed is again filtered off. The filtrate is just acidified with glacial acetic acid, the excess lead precipitated with hydrogen sulfide, and the lead sulfide filtered off. All the riboflavin is removed by this treatment. The filtrate is made to a volume of 1,000 ml. and stored under toluene in a refrigerator. One ml. of this preparation is equivalent to 100 mg. of the original yeast extract.

Strong and Carpenter⁷⁵ have produced a satisfactory yeast supplement by omitting the first filtration after addition of the basic lead acetate. Instead, the mixture was made alkaline with ammonia and was then filtered. This procedure is much less laborious.

Entirely satisfactory yeast supplements were also prepared from whole autolyzed yeast (Difco) rather than from yeast extract as originally recommended. These supplements have been used at a level equivalent to 20 mg. of the whole autolyzed yeast per tube.

Cystine: A solution of cystine hydrochloride containing one mg. per liter is prepared by suspending in water and adding the least possible amount of hydrochloric acid required to effect solution and then diluting to the required volume. It is stored under toluene.

Inorganic Salts: Solution A consists of 25 grams each of the mono- and di-potassium hydrogen phosphate dissolved in 250 ml. of water.

Solution B consists of 10 grams of $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$, 0.5 gram NaCl , 0.5 gram $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$, and 0.5 gram $\text{MnSO}_4 \cdot 4\text{H}_2\text{O}$ dissolved in 250 ml. of water.

75. Strong and Carpenter. 1942. Ind. Eng. Chem., Anal. Ed. 14, 909-913.

Standard Riboflavin Solutions: For a stock solution, pure crystalline riboflavin is accurately weighed and dissolved in warm 0.02 N acetic acid (12 grams glacial acetic acid per liter of water). A convenient concentration is 100 $\mu\text{g.}$ per ml. For use from day to day a more dilute (10 $\mu\text{g.}$ per liter) solution is prepared from the stock solution by diluting with water. These solutions must be carefully protected against sunlight which rapidly destroys riboflavin.

The assays are carried out in ordinary bacteriological test tubes (20 x 150 mm. is a convenient size). A metal wire rack which holds each tube separately and upright is very convenient but not necessary if the tubes are properly marked. Into each test tube dispense five ml. of the basal medium and a suitable aliquot of the riboflavin-containing extract. The contents of each tube are then diluted, when necessary, to give a total volume of 10 ml. Thus as much as five ml. of the extract to be assayed may be added. The volumes indicated should be measured with an accuracy of ± 0.1 ml. The tubes are plugged with cotton, sterilized in an autoclave at 15 pounds pressure for 15 minutes, and allowed to cool. They are then ready for inoculation.

Stock cultures of the organism may be carried as stabs in yeast extract agar containing one per cent glucose. For inoculum, a transfer is made to a sterile tube of the basal medium to which has been added 0.5 to 1.0 $\mu\text{g.}$ of riboflavin per 10 ml., previous to sterilization. The culture is incubated 24 hours at 37°C. (98.6°F.); the cells are centrifuged aseptically and resuspended in an equal volume of 0.9 per cent sodium chloride solution. Resuspension in twice their original volume of saline is also satisfactory. One drop (about 0.05 ml.) of this suspension is used to inoculate each assay tube. The inoculated assay tubes are incubated at 37°C. for one to three days.

With each set of assays there is set up a series of tubes (at least in duplicate) containing per 10 ml. of diluted medium, 0, 0.05, 0.10, 0.15, 0.20, 0.30, and 0.50 $\mu\text{g.}$ of riboflavin. These are inoculated and incubated along with the assay tubes. By measuring the response of *Lactobacillus casei* ϵ in these tubes, a standard curve may be constructed from which the riboflavin contents of the assay material may be computed.

Several methods may be used to determine the bacterial response to supplemental riboflavin. Snell and Strong⁶⁶ employed measurement of turbidity produced by the growth of the organism, using an Evelyn⁷⁶ photoelectric colorimeter with a 540 $m\mu$. filter, though other photoelectric colorimeters are suitable. The assay tubes must be well shaken to suspend all bacterial cells uniformly; medium and cells are transferred to the colorimeter tube or cuvette and the percentage of incident light transmitted is read directly from the galvanometer. However, it is pointed out that this method cannot be used when turbid or highly colored extracts are assayed. Corrections for the turbidity of extracts are not generally valid, since turbidity is frequently altered by the acid produced during the growth of the test organism.

A second method, which is probably more accurate and is generally applicable, is the titration of lactic acid produced during growth. Contents of the tubes may be transferred to 125-ml. Erlenmeyer flasks, the tubes rinsed thoroughly with water, and the combined solutions titrated with 0.1 N sodium hydroxide. Bromthymol blue is a satisfactory indicator, using two drops of a one-per cent alcoholic solution. Electrometric titrations, employing a glass electrode are very satisfactory. Silber and Mushett⁷⁷ have suggested that pH measurements after incubation may be used as an index of growth. A spread of about two pH units occurs over the range of the standard curve, 0.05 to 0.5 $\mu\text{g.}$ of riboflavin. These

76. Evelyn. 1936. J. Biol. Chem. 115, 63-75.

77. Silber and Mushett. 1942. J. Biol. Chem. 146, 271-272.

measurements were considered satisfactory after 24 hours' incubation and checked well with determinations made after 72 hours' incubation, both by pH measurement and direct titration.

Snell and Strong reported that maximum turbidity develops in the medium in approximately 24 hours, remaining constant for about 48 hours then slowly decreasing. Turbidity measurements are therefore best made at the end of 24 hours' incubation. Acid production increases steadily until about the third day, so titrations generally are made after 72 hours. Emmett, Bird, Brown, Peacock, and Vandenberg⁷⁸ reported precision results obtained by turbidity measurements at 24 hours and acidimetric determinations at 72 hours, irrespective of type or degree of potency of the sample.

The evaluation of the response of the organism in terms of riboflavin is most conveniently done by plotting the titration values (or photoelectric colorimeter readings) of the standards against micrograms of riboflavin per tube. From this standard curve, calculations are easily made for the riboflavin in the material under assay. Variations in the standard curve are relatively small from day to day.

To yield valid results the riboflavin content of the assay cultures must fall on the straight-line portion of the curve above 0.05 μg . riboflavin per tube, i.e., between 0.05 and 0.25 μg . per tube. Assays should be carried out at different levels, at least three. Only those assays giving concordant results at the different levels should be used. The values obtained at the different levels should be averaged for the final results.

PREPARATION OF BIOLOGICAL MATERIALS FOR ASSAY

Where possible, finely divided materials should be used. Extraction of riboflavin may be accomplished in several ways. For most materials autoclaving at 15 pounds pressure for 15 minutes in a large volume of water is recommended. Extractions may also be effected by boiling in 0.1 N hydrochloric acid or autoclaving with the acid, with subsequent neutralization, provided not more than 50 mg. of sodium chloride are added to the assay tubes with the aliquot to be assayed.

With some substances, especially those high in riboflavin and not containing interfering substances, suspensions of the materials after autoclaving may be added to the assay tubes without adversely affecting the results. For materials low in riboflavin and Fuller's earth adsorbates, Arnold, Lipsius, and Greene⁷⁹ followed the procedure of Supplee, Sender, and Jensen⁸⁰ using 80-per cent aqueous acetone as the extracting agent. The acetone was removed before dilution to volume.

Scott, Randall, and Hessel⁸¹ found poor agreement between the microbiological method and the Hodson and Norris⁸² fluorometric method in the case of wheat flour and flour enriched with riboflavin. In some cases

the values for recovery of added riboflavin by the former method amounted to 200 to 300 per cent recovery. They reported takadiastase treatment after autoclaving in 0.1 N hydrochloric acid would remove the stimulatory factor. Barton-Wright⁸³ found ptyalin gave more satisfactory results. Barton-Wright and Booth⁸⁴ have supplemented the medium with asparagine, xylose, nicotinic acid, and pantothenic acid. Xylose was reported to produce more concordant results between replicate tubes as well as a greater spread between concentration levels.

Andrews, Boyd, and Terry⁸⁵ noted appreciably lower values when the weight of the assay sample (cereals) increased. Centrifuging aqueous extractions decreased but did not eliminate this tendency; takadiastase treatment prior to removal of suspended solids resulted in lower values, but riboflavin recoveries remained high. If it is assumed that added riboflavin is quantitatively recovered, the values representing the difference between total flavin found and that added may be a measure of the growth factors or "apparent flavin." Thus the difference between the flavin values from assay of centrifuged aqueous extractions treated with takadiastase and the value obtained for "growth factors" gives a riboflavin value in close agreement with those found by fluorometric determinations on samples before and after takadiastase treatment. Gluten, a major constituent of flour, was inactive as a stimulating agent, Bauernfeind, Sotier, and Boruff⁸⁶ found aqueous or 0.1 N hydrochloric acid extracts of riboflavin from meat scraps, fish meal, distillers' dried solubles, and liver meals contained stimulatory agents. The stimulating agents could be removed from the extraction residues or from the assay material previous to riboflavin extraction by lipid solvents, such as acetone, methyl alcohol, and methyl ether. Addition of these latter extracts to the basal medium in the presence of riboflavin resulted in abnormally high recoveries of the vitamin. Fatty acids containing 16-carbon atoms or more were markedly stimulatory as were their esters and calcium salts. A 12-carbon alcohol, 12-, 15-, and 16-carbon aldehydes, an 11-carbon lactone, lecithin, and fusel oil residues also produce appreciable stimulation. Many of these same extracts and compounds produced the same effect in the microbiological pantothenic acid assay. Bauernfeind *et al.* pointed out that agreement of results at different levels of assay is not always a good index of the absence of stimulatory agents; the amount of such agents is a contributing factor. If the stimulation occurs at different levels along the linear portion of the curve, agreement of results at different levels may occur. These authors recommended elimination of stimulatory agents through one of the following procedures: (1) the use of clarified extracts, (2) preliminary extraction of the dried samples with a lipid solvent after which an autoclaved aqueous suspension of the product may be used for assay, (3) inclusion of photolyzed extracts of the product in the riboflavin basal medium or the inclusion of an alkaline- or acid-treated extract of the product in the

pantothenic acid medium, as was previously suggested by Eckhard, György, and Johnson⁸⁷ who found such a procedure satisfactory when assaying blood for riboflavin. However, Wegner, Kemmerer, and Fraps⁸⁸ reported addition of alkaline-photolyzed extracts of rice bran, wheat bran, and whole-wheat flour was not feasible owing to the inability to standardize the response when the extracts are in the medium. Alkaline-photolyzed extracts of whole-wheat flour produced more exaggerated acid production by *Lactobacillus casei* in the presence of lower levels of riboflavin. Materials removed by ether extraction stimulated acid production but the enhancing value of the photolyzed solution was reduced only slightly. These factors suggested that photolysis at pH 11 produced a substance which stimulated acid production by the test organism. Wheat-flour extracts which had been passed through florisil at pH 6.7 to remove riboflavin did not contain the substance activated by photolysis but did contain a factor capable of exerting some stimulation. Concentrated extracts of rice bran, wheat bran, or whole-wheat flour passed through florisil to remove riboflavin and then added to assay tubes containing one $\mu\text{g.}$ of riboflavin caused production up to 20.6 ml. of 0.1 N acid, which is well beyond the 9 to 10 ml. previously considered the maximum. Addition of a similar amount of the concentrate to the 0.05- $\mu\text{g.}$ level of riboflavin produced 6.9 ml. of 0.1 N acid. Addition of pyridine to the assay tubes also caused stimulation of acid production.

Since numerous methods have been proposed for overcoming the presence of stimulatory and inhibitory substances in certain materials, notably cereals, Strong and Carpenter⁷⁵ compared some of the proposed methods with others of their own initiation. Direct assay of whole-wheat flour after hydrolysis with 0.1 N hydrochloric acid by autoclaving showed a wide drift in riboflavin values depending on the amount of assay material present, with a tendency toward decreasing values in the presence of increasing amounts of the assay material. Similar, but more striking, are the results obtained by assaying cornstarch (which contains less than 0.20 $\mu\text{g.}$ of riboflavin per gram) to which had been added five $\mu\text{g.}$ per gram of riboflavin. Direct assay after hydrolysis in 0.1 N acid by autoclaving gave values ranging from 9.5 to 1.4 $\mu\text{g.}$ per gram (1 ml. and 4 ml. of suspension per tube, respectively). The method of Scott *et al.*,⁸¹ involving takadiastase treatment previous to autoclaving, was unsatisfactory in removing the stimulatory agent. The method of Andrews, Boyd, and Terry⁸⁵ and those suggested by Strong and Carpenter gave results which checked well at all levels of assay material. Assay for riboflavin in the presence of ether-soluble extracts of cornstarch resulted in high and variable values decreasing as the amount of the extract increased. The following two procedures were found satisfactory in removing the stimulating agents.

Procedure 1: A weighed sample containing approximately 10 $\mu\text{g.}$ of riboflavin was suspended in 50 ml. of 0.1 N HCl and the suspension autoclaved for 15 minutes at 15 pounds pressure. After cooling the autoclaved suspension was adjusted to pH 4.5 (or until a heavy precipitate appeared) with 2.5 N sodium acetate solution, and the volume

made to 100 ml. The mixture was filtered by pouring repeatedly through a fluted, No. 40 Whatman filter paper until a clear filtrate resulted. A 50-ml. aliquot of the filtrate was adjusted to pH 6.6 to 6.8 and diluted to 100 ml. before assay. In the case of a few samples it was advantageous to filter a second time after the pH had been adjusted to 6.6 to 6.8.

Procedure 2: This was the same as above, except that the 50-ml. aliquot of the first filtrate was shaken out three times with 30-ml. portions of ether. Without removing dissolved ether the aqueous phase was adjusted to pH 6.6 to 6.8 and diluted to 100 ml., and the aliquots were added directly to the assay tubes.

Strong and Carpenter⁷⁵ also confirmed Bauernfeind *et al.*⁸⁶ with regard to the stimulating activity exhibited by various fatty acids. The effect was found to depend on the absolute amounts of riboflavin and fatty acid present in the tube and also on the ratio between the two. Very marked effects were noted at ratios of 1:500 and 1:1,000. In general the greatest effects were noted at the lowest levels of riboflavin. Oleic and stearic acid markedly stimulated the bacterial response while palmitic acid and particularly linoleic acid acted as potent inhibitors. Bauernfeind *et al.* found linoleic acid to inhibit and stimulate growth, depending on its concentration. Mixtures of fatty acids also gave high results. On the other hand, neutral fats have little disturbing influence on the riboflavin assay. Lecithin gave considerable stimulation when the ratio of riboflavin to lecithin was high. Synthetic wetting agents, sodium salts of various alkyl sulfo-succinic acid esters, which lower surface tension of neutral solutions, proved to be inert at the concentrations tested. Wegner, Kemmerer, and Fraps⁸⁹ observed the precipitation at pH 4.5 following acid hydrolysis resulted in more reliable riboflavin assays on wheat products. Results of comparative investigations of microbiological and fluorometric methods for riboflavin in patent flour, enriched flour, and dried yeast were reported by Kemmerer⁹⁰ and Andrews.⁹¹ Microbiological methods were found to be satisfactory.

Association of Official Agricultural Chemists' Method for Assaying Foods for Riboflavin.⁹² The following procedure is a tentative one for determination of riboflavin in yeast and dried skim milk, modified for wheat flours or other materials containing less than 10 parts per million of riboflavin.

To 10 grams of whole-wheat or white flour add about 140 ml. of 0.1 N HCl. Mix well and autoclave 15 minutes at 15 pounds pressure. Cool to room temperature. By means of a pH apparatus adjust the pH to 4.5 with 1 N NaOH. Filter the sample carefully, pouring the first few milliliters that come through back onto the filter paper. Wash the precipitate two times with 10-ml. portions of distilled water buffered with one ml. of phosphate solution (J.A.O.A.C. 1941, 24, 413) and adjust to pH 4.5 with 0.1 N HCl. Adjust the pH of the filtrate to 6.6 to 6.8 and dilute to 200 ml. Assay the solutions at two or more levels, such as two and three ml. for whole-wheat flour and three and four ml. for white flour, using four tubes on each level. Set up standard tubes (four on each level) on 0.0, 0.05, 0.10, 0.15, and 0.20 microgram levels of riboflavin.

McIntire, Schweigert, Henderson, and Elvehjem⁹³ applied the following riboflavin extraction procedure to meats. Two grams of meat were homogenized in N/10 sulfuric acid. Then 0.2 gram clarase and 0.2 gram papain were added in five ml. of 2.5 M sodium acetate, followed by 24 hours' incubation at 37°C.(98.6°F.). The samples were

autoclaved, neutralized, and filtered. The filtrates were extracted with ether according to the method of Strong and Carpenter; the aqueous layer was transferred to 100-ml. volumetric flasks and made to volume. Suitable aliquots were then taken for assay. Papain preparations contain negligible amounts of riboflavin but clarase preparations contained about 0.45 μ g. per gram, so corrections are necessary in calculating the riboflavin content of the samples.

Thus it seems that variations in riboflavin calculated from different assay levels with certain products can be attributed to free fatty acids present in the substance being tested. Inhibition and stimulation may be produced by the same substances; substances which stimulate an organism at one concentration may have the reverse activity at a higher concentration. Strong and Carpenter pointed out that oleic acid has been reported stimulatory for the diphtheria bacillus (Cohen, Snyder, and Mueller⁹⁴) in concentrations in the same order as for *Lactobacillus casei* by themselves and Bauernfeind, Sotier, and Boruff.⁸⁶

Results of investigations by Bauernfeind *et al.* and Strong and Carpenter showed that preparation of cereals and certain other samples for microbiological riboflavin assays should consist of two main steps—(1) hydrolysis, and (2) a procedure designed to remove fat-soluble interfering substances. It was pointed out that hydrolysis should be sufficiently drastic to decompose various combined forms of riboflavin and thus reduce the problem to determination of a single compound, though the method has been shown to measure some combined forms of the vitamin.⁷² Others may exist which are not measured. Also riboflavin itself is less likely to be lost in subsequent precipitations than certain combined forms, such as riboflavin phosphate which has been shown to have a greater affinity for at least one protein than does riboflavin.⁹⁵ The removal of interfering substances from the hydrolysate can be accomplished successfully in most cases by careful filtration. Ether extraction is equally effective but is complicated by emulsion formation, if much solid matter is present, and is time consuming (for routine assays). Such extractions are desirable in the case of high-fat materials, such as cheese, fish meal, etc. Obviously extraction must follow the hydrolysis to remove fatty acids thereby liberated. Similar treatment of samples has been satisfactory in removing stimulatory factors affecting the microbiological assay method for pantothenic acid, which also uses *Lactobacillus casei* as the test organism. The assay for nicotinic acid, employing *Lactobacillus arabinosus*, is but little disturbed by fatty acids.

Feeney and Strong⁹⁶ have reported stimulation of the assay organism by l-asparagine in a medium free of yeast supplement. A mixture of adenine, guanine, and the "norite eluate factor" also exerted some activity and, when combined with asparagine, maximum stimulation was observed. Thus this latter mixture could, under certain conditions, replace the norited yeast supplement. In much higher concentrations, glutamine was also active. Glutamine and asparagine together produced maximum stimu-

lation, but glutamic acid was strongly inhibitory and at a level of 18 mg. per tube completely inhibited growth. Aspartic acid also nullified the stimulatory effect of asparagine but not that of glutamine or glutamic acid. Glutamine would even counteract inhibition caused by aspartic acid.

In the assay for riboflavin 100 μ g. of adenine and guanine were inhibitory, 2.5 mg. of asparagine per tube produced a definite decrease in bacterial response, and aspartic acid was inert at a level of 4.4 mg. per tube. Inhibition was sufficient to cause an error of 20 per cent in riboflavin assays. However, Feeney and Strong point out that the effects of these inhibitory and stimulatory compounds are obtained at such high concentrations that they are of no practical importance in the riboflavin assay. Bauernfeind *et al.*⁸⁶ detected no action by asparagine at levels of five mg. per tube.

Fraser, Topping, and Isbell⁹⁷ applied the microbiological method to the assay of riboflavin in urine and tissue of riboflavin-depleted dogs and rats. Assays of urines of certain dogs showed considerable "drifting" which was later shown to be due to the presence of urea.⁹⁸ Blood was successfully assayed by Strong, Feeney, Moore, and Parsons⁹⁹ by direct assay after a five to tenfold dilution. In assay tubes containing more than 0.2 ml. of blood, large amounts of red-brown, fibrous, solid material were present interfering with the titration and apparently inhibiting normal growth of the organism, perhaps owing to fatty acids, as noted by Strong and Carpenter.⁷⁵ Quantitative extractions of riboflavin from blood were also obtained by the following procedure:

A mixture of 15 ml. of human blood, 100 ml. of water, and one ml. of 10-per cent hydrochloric acid was centrifuged one hour, and the supernatant liquid decanted from the small gummy precipitate. The supernatant liquid was stirred for one-half hour with two grams of Lloyd's reagent (hydrous aluminum silicate), centrifuged, and the adsorbent combined with the above precipitate. The filtrate which still contained the bulk of the blood solids contained no riboflavin, and when known amounts of riboflavin were added to it, quantitative recoveries were obtained. The combined adsorbent and precipitate were found to contain riboflavin equivalent to 0.64 μ g. per ml. of the original blood. Direct assay of the blood gave 0.54 μ g. per ml. No difficulties were encountered in the assay of urine directly. Over 98 per cent of the riboflavin could be removed by adsorbing on Lloyd's reagent; the riboflavin thus adsorbed could be successfully assayed by adding the adsorbate directly to the assay tubes. Andrews, Boyd, and Terry⁸⁵ obtained quantitative recoveries of pure riboflavin after adsorption on Fuller's earth, when assayed as the solid.

PANTOTHENIC ACID

The function of this vitamin is unknown, though presumably it is associated with some enzyme system. Chicks on pantothenic acid-free diets suffer from a specific dermatitis. Incrustations occur about the eyes, corn-

99. Strong *et al.* 1941. J. Biol. Chem. 137, 363-372.

ers of the mouth, and areas between the toes. Feathering is retarded. Hatchability of eggs is influenced by pantothenic acid though egg production is apparently not decreased by a deficiency. Retardation of growth in rats, mice, pigs, and chicks results from a deficiency. Depigmentation of fur of animals has been attributed to pantothenic-acid deficiencies though other factors apparently are involved also. Typical skin lesions may appear. Nervous and endocrine systems may be involved. The role in human physiology is uncertain, but its present status is reviewed by Gordon.¹⁰⁰ Some of the pertinent information has been summarized by Waisman³¹ as follows:

Pantothenic Acid (chick antidermatitis factor, filtrate factor, etc. $C_8H_{17}O_5N$, N-(α,γ ,dihydroxy- β,β ,dimethylbutyryl)- β -amino-propionic acid).

Properties: Water-soluble, stable to heat, destroyed by strong acids or alkalis, occurs in natural materials in combined form.

Function: Role in normal metabolism is unknown.

Symptoms Associated With Deficiency: Precise role in human physiology not established.

Requirement: Unknown, but animal experiments indicate it to be somewhere between thiamin and nicotinic acid figures.

Occurrence in Natural Foodstuffs: Chiefly brewers' yeast (dry), liver, egg yolk, and peanuts.

The chemistry and biochemistry of pantothenic acid has been reviewed by Williams.¹⁰¹

In the concentration of pantothenic acid, Williams and Saunders¹⁰² employed a yeast-growth method for assaying for the vitamin. Snell, Pennington, and Williams¹⁰³ have shown that the *Lactobacillus* method gives reasonably good agreement with the yeast method. Pennington, Snell, Mitchell, McMahan, and Williams^{103a} more recently stated that the yeast method, when applied to the assay for pantothenic acid in crude tissue extracts, was not as specific as the bacteria method. Atkin, Schultz, Williams, and Frey¹⁰⁴ suggested a simpler method using yeast which is described in detail in the discussion of pyridoxine later in this chapter. The bacteria methods have been widely adopted because of simplicity. Snell and Wright¹⁰⁵ have stated that their nicotinic acid assay method, using *Lactobacillus arabinosus* 17-5, may be slightly modified to permit its use in assaying for pantothenic acid. Landy and Dicken⁶⁸ proposed a method using *Lactobacillus casei* ϵ similar to those proposed by Pennington *et al.* and Strong *et al.* Silber and Unna's¹⁰⁶ pantothenic acid medium was essentially the medium of Snell and Strong for riboflavin assay except that the yeast-extract supplement was replaced with thiamine, 10 μ g.; pyridoxine, 10 μ g.; nicotinic acid, 10 μ g.; and riboflavin, 1 μ g. Assays with this medium agreed within experimental error with similar assays in which the yeast-extract supplement was used. Assays for riboflavin were performed

exactly as those for pantothenic acid except that riboflavin supplement of one microgram per tube was replaced with one microgram of pantothenic acid.

Pelczar and Porter's¹⁰⁷ Method for Microbiological Assay for Pantothenic Acid. This is based on the requirement of *Proteus morganii* for pantothenic acid. In presence of pantothenic acid the organism can grow well in an inorganic salt medium. More luxuriant growth is obtained on glucose-meat infusion medium. The authors were unable to secure as good growth on the inorganic salts medium by the addition of other known factors, so the medium was supplemented with alkali-treated proteose peptone.

The basal medium is prepared as follows: A solution of 4.5 grams of K_2HPO_4 , 0.5 gram $(NH_4)_2SO_4$, and 0.5 gram NH_4Cl is adjusted to pH 7.4, the volume is adjusted to a liter with distilled water, and is autoclaved.

To 950 ml. of this medium are added aseptically:

Fe(SO ₄)(NH ₄) ₂ SO ₄ ·6H ₂ O.....	(0.002 M in 0.002 M HCl)	20 ml.
MgSO ₄ ·7H ₂ O.....	(0.4 per cent in water)	10 ml.
Glucose.....	(50 per cent in water)	10 ml.
Nicotinic acid.....	(0.001 M in water)	10 ml.
Cystine.....	(0.15 M in 0.1 M HCl)	10 ml.
Alkali-treated proteose peptone.....		10 ml.

Alkali-Treated Proteose Peptone: The alkali-treated proteose peptone is prepared by dissolving Bacto-proteose-peptone to a concentration of 10 per cent in N sodium hydroxide and autoclaving at 15 pounds for one hour to effect complete inactivation of the pantothenic acid. Neutralize with glacial acetic acid, filter to remove the precipitate, and finally autoclave for 10 minutes at 15 pounds. This serves as the stock solution.

The basal medium is dispensed in 10-ml. amounts in sterile cotton-plugged test tubes.

With each group of assays run, it is necessary to establish a standard curve by plotting growth of the test organism as measured by the turbidity produced against the amounts of calcium pantothenate in the respective tubes, ranging from 0.0001 to 0.001 μ g. per ml. of basal medium.

In applying the method to biological material, finely ground specimens (the method of Potter and Elvehjem¹⁰⁸ is convenient) are autoclaved at 15 pounds pressure for 30 minutes at neutrality with a large volume of water, after which any voluminous precipitate is removed by filtration through paper. The filtrates are then autoclaved again for 10 minutes to sterilize, and serve as the stock material for assay. Suitable volumes of extracts to be assayed are added to the basal medium (the authors used up to 0.8 ml.); the tubes are inoculated and incubated.

In most instances no interference was reported by opacity or color of the extracts since dilution serves to reduce this error. However, when opacity or color is imparted to the assay medium it is necessary to clarify by an absorbing agent such as kieselguhr.

The inoculum is prepared by transferring *Proteus morganii* from a 24-hour agar slant to 10 ml. of the basal medium containing 0.0005 μ g. calcium pantothenate per ml. After 24 hours' incubation one drop of this culture is transferred to 10 ml. of similar medium. One drop of this second subculture is used to inoculate the assay tubes. After 24 hours' incubation the response to pantothenic acid contained in the assay material is determined by a suitable photoelectric turbidimeter, and the pantothenic acid concentration is computed from the standard curve.

Proteus morganii requires the intact pantothenic acid molecule. No growth occurs when its components, β -alanine and α -hydroxy, β -dimethyl- α -butyrolactone, are substituted. Dorfman, Berkman, and Koser¹⁰⁹ have recently shown that in the metabolism of

107. Pelczar and Porter. 1941. J. Biol. Chem. 139, 111-119; Soc. Expt. Biol. and Med. Proc 43, 151-154.

108. Potter and Elvehjem. 1936. J. Biol. Chem. 114, 495-504.

109. Dorfman, Berkman, and Koser. 1942. J. Biol. Chem. 144, 393-400.

the test organism, the vitamin is involved in the pyruvic acid metabolism, presumably to acetic acid, though the possibility that it acts on some other metabolic step involving pyruvic acid or some intermediate derived from pyruvic acid has not been eliminated.

Pennington, Snell, and Williams'¹¹⁰ **Microbiological Assay for Pantothenic Acid.** This method employs *Lactobacillus casei* ϵ (American Type Culture Collection No. 7469). The general technic is much the same as that in the Snell and Strong method for riboflavin assays.

The basal medium is composed of the following constituents, the concentration of which refers to the final dilution. For assay purposes, it should be made up in double this concentration.

Alkali-treated peptone.....	0.5	per cent
Glucose.....	1.0	per cent
Sodium acetate.....	0.6	per cent
Alkali-treated yeast extract, equivalent to yeast extract.....	0.1	per cent
Acid hydrolyzed casein, equivalent to casein.....	0.2	per cent
Cystine.....	0.01	per cent
Riboflavin.....	0.01	mg. per cent
Inorganic salts, Solutions A and B.....	5.0	ml. each
Adjust pH to 6.6-6.8		
Distilled water to make 1 liter		

The constituents of the medium are prepared as follows:

Alkali-Treated Peptone: Forty grams of Bacto-peptone in 250 ml. of water are treated with 20 grams of sodium hydroxide dissolved in 250 ml. of water. The mixture (1 N in NaOH) is allowed to stand at room temperature for 24 hours. The sodium hydroxide is neutralized with glacial acetic acid (27.9 ml.), seven grams of anhydrous sodium acetate (11.6 grams of the hydrate) are added, and the mixture is diluted to 800 ml. The solution may be preserved under toluene.

(Note: This is the same alkali-treated peptone used in the Snell and Strong riboflavin assay method.)

Acid-Hydrolyzed Casein: Fifty grams of casein are mixed with 250 ml. of 25-per cent sulfuric acid. The mixture is autoclaved for 10 hours at 15 pounds pressure. The sulfuric acid is removed with barium hydroxide (341 grams of $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$). Any excess barium ion is carefully removed with sulfuric acid, and the pH adjusted to 7 with sodium hydroxide. The solution is made to a volume of 450 ml., autoclaved for 10 minutes, and filtered. It is preserved under toluene.

The removal of large amounts of barium sulfate from the above solution is often tedious. An alternative procedure for preparing hydrolyzed casein has been shown satisfactory by the Texas workers and is generally preferred because of its simplicity. Fifty grams of commercial vitamin-free casein is mixed with 500 ml. of approximately constant boiling hydrochloric acid (prepared by mixing equal parts of concentrated hydrochloric acid and distilled water). The mixture is boiled under reflux for eight to 10 hours and the acid removed by vacuum distillations to a sirup. The process is repeated after dilution with water. The sirup is dissolved in water, neutralized with sodium hydroxide, and diluted to 500 ml.

Alkali-Treated Yeast Extract: A solution of 20 grams of Difco yeast extract in 200 ml. of 0.05 N sodium hydroxide is autoclaved at 15 pounds pressure for 30 minutes. The solution is neutralized with glacial acetic acid, autoclaved an additional 10 minutes to coagulate precipitated proteins, and filtered. The volume is adjusted to 200 ml. (100 mg. per ml.) and the solution preserved under toluene.

Inorganic Salts: Solution A consists of 25 grams of potassium monohydrogen phosphate and 25 grams of potassium dihydrogen phosphate dissolved in 250 ml. of water.

110. Pennington *et al.* 1940. J. Biol. Chem. 135, 213-222.

Solution B consists of 10 grams of magnesium sulfate heptahydrate, 0.5 gram of sodium chloride, 0.5 gram of ferrous sulfate heptahydrate, and 0.5 gram of manganese sulfate tetrahydrate dissolved in 250 ml. of water. Salts precipitate from Solution B when it stands in air; it need be renewed only when a uniform suspension can no longer be secured by shaking. It has been stated that a few drops of concentrated hydrochloric acid added to Solution B will prevent precipitation.¹¹¹

Procedure: The procedure is much the same as employed in the microbiological assay for riboflavin of Snell and Strong. Test tubes are supported in a wire or metal rack, which may be autoclaved. Five ml. of the basal medium (twice the concentration in the above table) are dispensed into each tube along with suitable aliquots of the samples under analysis (not exceeding five ml.). All tubes are made to a volume of 10 ml. with distilled water. The tubes are plugged with cotton and sterilized at 15 pounds pressure for 15 minutes. After cooling to room temperature, they are ready for inoculation.

With each set of assay tubes a series of tubes containing known amounts of d-calcium pantothenate are set up. The following levels are satisfactory to establish the standard curve: 0, 0.01, 0.02, 0.05, 0.10, and 0.20 μ g. pantothenate per tube. The volume is then adjusted to 10 ml. These tubes are sterilized at 15 pounds and inoculated at the same time as the assay tubes.

The inoculum is prepared by centrifuging the cells from a 24-hour culture grown in the basal medium containing 0.20 μ g. calcium pantothenate, and resuspending in double the original volume of 0.9 per cent saline solution. A drop of this suspension is used as the inoculum. All tubes after inoculation are incubated at 37°C. (98.6°F.) for 24 to 72 hours, depending on the method employed for measuring the response.

The response to pantothenic acid may be measured by turbidimetric measurements after 24 hours' incubation using a photoelectric colorimeter. Caution must be exercised to suspend all cells before measurements are taken; or, after 72 hours' incubation, the lactic acid produced by the test organism may be titrated. Pennington, Snell, and Williams recommended using a glass electrode because of the color of the medium and its buffer capacity, or diluting the medium and titrating, using brom thymol blue as the indicator. More recently Silber and Mushett¹¹² have employed direct pH measurements at either 24 or 72 hours with good results.

The following microtechnic has been employed when only minute amounts of material are available for assay.^{103a}

Cultures are grown in the depressions of white porcelain spot plates. The depressions are moistened with 10-per cent benzene solution of paraffin which facilitates handling of the solution to be added later. The spot plates, each with a plate glass cover to fit, are then supported in a basket covered with cloth towel and autoclaved. The medium, etc. are measured with the aid of a 0.1-ml. graduated pipette drawn to a needle-like point and controlled by a hypodermic syringe attached by a length of rubber tubing to the opposite end. The standard pantothenic acid solutions and a solution for analysis are added to the depressions in the spot plates. Standard depressions containing 0, 0.0002, 0.0004, 0.001, 0.002, and 0.004 μ g. of calcium pantothenate are satisfactory to establish to the standard curve.

Various amounts of tissue extract must be selected to contain approximately 0.0002 to 0.001 μ g. of pantothenic acid. Volumes up to 0.1 ml. may be used. The contents of each depression are then diluted if necessary to 0.1 ml.

The cells from a 24-hour culture of inoculum grown as in the above method are centrifuged out aseptically and washed by centrifuging twice in 0.9 per cent saline solution. With the aid of a sterile pipette the resuspended organisms are transferred to the previously sterilized basal medium (one drop per five ml.). After thorough shaking, 0.1 ml. of this medium thus inoculated with *Lactobacillus casei* ϵ is added to each depression in the spot plates. The sterile cover plates are then sealed with Scotch tape. The spot plates are then placed in a 37°C. incubator for an incubation period of 48 hours.

111. Lewis. 1942. J. Biol. Chem. 146, 441-450.

112. Silber and Mushett. 1942. Idem 146, 271-272.

Titration of lactic acid produced during growth is employed as a measure of the response to pantothenic acid. A Kirk¹¹³ microburette is employed containing 0.1 N alkali. The end point is determined electrometrically using a special micro saturated calomel half cell and a platinum electrode. Quinhydrone is added to the solution before titration and the progress of the titration is followed with a galvanometer sensitive to 0.15 micro-amperes per mm. division.

A standard curve is obtained with each set of assays. The samples for assay are dosed at increasing levels of concentration and the pantothenic acid content of each unknown is read from the standard curve. Usually three concordant results at different levels are averaged to obtain a final figure. These results usually agree with each other at least within ± 10 per cent.

Morgareidge, Flower, and Edel¹¹⁴ have noted some variations in the ability of the basal medium to support growth of *Lactobacillus casei*, which was attributed to the acid-hydrolyzed casein and autoclaved or charcoal-treated yeast extract. Rice-bran concentrate was found to be an efficient substitute containing other unknown growth factors for this organism and to be easily freed of pantothenic acid. Such a medium gave consistent results over a fifteenfold range of assay levels.

Strong, Feeney, and Earle's Method¹¹⁵ for Microbiological Assay for Pantothenic Acid. Strong, Feeney, and Earle also proposed a microbiological assay method for pantothenic acid using *Lactobacillus casei* as the test organism. It is very similar to the method of Pennington *et al.*, but differs slightly with respect to the basal medium. The basal medium contains the following ingredients:

Sodium hydroxide-treated peptone.....	0.5	per cent
Sodium acetate.....	0.6	per cent
Glucose.....	1.0	per cent
Cystine.....	0.01	per cent
Asparagine.....	0.025	per cent
Riboflavin.....	100.0	μ g.
Inorganic salts, Solutions A and B.....	5.0	ml. each
Yeast supplement, equivalent to autolyzed yeast.....	5.0	grams
pH adjusted to 6.6-6.8		
Distilled water to make 1 liter		

This is the composition of the final diluted medium. For assay purposes it is prepared double strength, five ml. are dispensed in test tubes, and aliquots of the sample to be assayed (not more than five ml.) are added. The contents of each tube are then diluted to a volume of 10 ml. The tubes are then plugged with cotton and sterilized at 15 pounds pressure for 15 minutes. With each set of assays, standards are prepared containing the following amounts of d-calcium pantothenate per tube: 0, 0.025, 0.05, 0.075, 0.100, 0.125, and 0.150 μ g.

CONSTITUENTS OF THE MEDIUM

Yeast Supplement: A solution of 25 grams of whole autolyzed bakers' yeast, obtained from Difco Laboratories, Inc., Detroit, Michigan, in 500 ml. of water is adjusted to pH 1.5 with concentrated hydrochloric acid and 25 grams of activated charcoal (Norite A) are added. The mixture is stirred for 20 minutes at room temperature and the charcoal removed by either centrifuging or filtering with suction. In the latter case a 0.5-cm. layer of moistened Filter-Cel (Johns-Manville, standard) is used on the paper. In either case the Norite is not washed, and a small amount of

113. Sisco, Cunningham, and Kirk. 1941. J. Biol. Chem. 139, 1-10.
114. Morgareidge, Flower, and Edel. 1943. Abs. of papers read before Amer. Chem. Soc. April 12-15, 1943.
115. Strong, Feeney, and Earle. 1941. Ind. Eng. Chem., Anal. Ed. 13, 566-570.

charcoal coming into the filtrate on centrifuging is disregarded. The pH of the liquid is readjusted to 1.5 and the adsorption is repeated as before. The solution is then brought to neutrality with sodium hydroxide, filtered to remove any charcoal present, and diluted to 1,000 ml. One milliliter of the final solution is thus equivalent to 25 mg. of autolyzed yeast. It is desirable that the preparation of the yeast supplement be carried through as rapidly as convenient, so that the solution is not kept strongly acid for longer than one to two hours. This preparation is stored under toluene in the refrigerator.

Asparagine: A one-per cent aqueous solution of l-asparagine monohydrate is prepared, and stored under toluene.

Sodium Hydroxide-Treated Peptone: This is the same preparation used in the Snell and Strong procedure for riboflavin and by Pennington *et al.* in their pantothenic acid assay.

Salt Solutions: These also are the same as used in the above-mentioned assays.

Calcium Pantothenate Standard Solutions: Standard solutions of d-calcium pantothenate are prepared in 0.05 M phosphate buffer (pH 6.8 to 7.0). One is diluted to a concentration of 50 μ g. per ml. from which a second is prepared containing 0.5 μ g. per ml. The former is used to replenish the latter, which in turn is used from day to day in setting up assays. Aliquots are diluted accurately with water for setting up the standard curve. Solutions are preserved under toluene in a refrigerator.

More recently Neal and Strong¹²² have reported that the best response to pantothenic acid is obtained when the inoculum is grown directly from the stab culture. Also, weekly instead of monthly transfers of the stab culture are recommended.

A slight modification¹²² of the medium of Strong, Feeney, and Earle is recommended to produce greater growth response to pantothenic acid and to reduce the tendency for "drifts" in results of assays of certain substances, notably brans, which contain water-solubles^{88, 123, 124} capable of stimulating the bacterial response. The sodium acetate concentration was increased two per cent, the yeast extract concentration doubled, glutamic acid added in a concentration of 0.25 per cent and Vitab supplement equivalent to .0075 per cent Vitab is added. These concentrations refer to the final diluted medium.

Yeast Supplement: This was prepared as before¹¹⁵ except that Darco G-60 was used for the adsorption, and the adsorption was carried out in a volume of 240 ml. After the second charcoal treatment the filtrate was neutralized with solid sodium hydroxide and diluted to 250 ml. The supplement was thus four times as concentrated as previously described, since each milliliter was equivalent to 100 mg. of whole autolyzed yeast.

Vitab Supplement: Seventy-five grams of Vitab (National Oil Products Co.) were dissolved in 500 ml. of water, the pH was adjusted to 1.2 to 1.5 with concentrated hydrochloric acid, and the mixture was stirred with 50 grams of activated charcoal (Darco G-60) for 20 minutes at room temperature. The charcoal was filtered off, the pH readjusted to 1.2 to 1.5 and the adsorption repeated. The filtrate was neutralized to pH 6.8 with concentrated sodium hydroxide, filtered again and diluted to 1,000 ml. with distilled water. One milliliter of the final solution therefore contained the equivalent of 75 mg. of Vitab.

Preparation of Samples for Assay: These methods apply to both *Lactobacillus* methods for assaying for the vitamin. Extracts of natural materials may be prepared by autoclaving for 30 minutes at 15 pounds pressure finely ground or homogenized samples (Potter and Elvehjem¹⁰⁸) at neutrality with a large volume of water. Acid or alkali inactivates pantothenic acid by cleavage.^{115a} Pennington, Snell, and Williams¹¹⁰ found

115a. Weinstock, Mitchell, Pratt, and Williams. 1939. Am. Chem. Soc. J. 61, 1421-1425.

certain materials did not give results agreeing satisfactorily when calculated at different assay levels. Among these were urine, oysters, and mushrooms. The variations could be overcome by adding to the basal medium a pantothenic acid-free supplement, prepared by acid treatment, of the sample in question. In the case of urine this supplement was prepared by making the urine 0.5 N with sulfuric acid, and autoclaving at 15 pounds pressure for 15 minutes. Excess sulfate was removed with barium hydroxide. With oysters and mushrooms the supplements were prepared by a similar treatment of aqueous extracts equivalent to 100 mg. per ml. of the fresh tissue. The supplements were added to the basal medium in approximately ten times the highest concentration used for the assay sample.

Blood was assayed by Strong, Feeney, and Earle¹¹⁵ by diluting fivefold and assaying directly without autoclaving. These workers also assayed directly other liquid materials, such as milk and urine which are easily and completely soluble in water, by diluting a convenient volume and neutralizing if necessary. No inhibition was noted with urine.

Certain materials, such as yeast and animal tissues, contain a "combined form" of pantothenic acid which is not available for *Lactobacillus casei*. Some chick assays on such materials have been much higher than reported by microbiological methods (Strong, Feeney, and Earle¹¹⁵). In order to determine the total pantothenic acid content of animal tissues and yeast samples it is necessary first to subject them to autolysis or to an enzyme digestion. Wright *et al.*,¹¹⁶ following the suggestion of Pennington, Snell, and Williams, allowed animal tissue to autolyze for 24 hours under benzene, after homogenization according to the method of Potter and Elvehjem, or using a Waring blender. Strong, Feeney, and Earle employed 48-hour incubation at 37°C. of a slightly acid (pH 5) aqueous suspension of one part of the sample and two parts of clarase powder. Fruits, vegetables, cereals, eggs, and dairy products did not show any significant increase in apparent pantothenic acid content when subjected to this treatment. Waisman, Henderson, McIntire, and Elvehjem¹¹⁷ have shown hot water extraction (autoclaving) of animal tissues gave erratic pantothenic acid values. Homogenization, followed by autoclaving at the natural pH, gave more consistent results. Pepsin digestion of both fresh and dried samples of the same tissues following homogenization gave higher values than untreated fresh or dried tissues. Autolysis gave practically equal values on fresh tissues. Equal weights of animal tissue and clarase and twice as much clarase gave higher values than pepsin treatment. Pancreatin (Merck) appeared to give even better extraction because it gave more complete liquefaction. None of these enzyme preparations had any effect on the amide linkage of the vitamin and each furnished only insignificant amounts of pantothenic acid. Pancreatin digests were made in buffered solutions (pH 7.0 to 7.5) so no pantothenic

117. Waisman *et al.* 1941. J. Nutr. 23, 239-248.

acid was destroyed either by acid or alkali. With some tissues clarase gave just as good liberation. Cheldelin, Eppright, Snell, and Guirard¹¹⁸ have also used enzymic liberation of pantothenic acid, comparing autoclaving, autolysis at natural pH, and the following enzyme preparations at their optimum pH: takadiastase, malt diastase, pancreatin (24 hours at 37°C.), and three hours digestion with takadiastase followed by five hours with papain at 45 to 57°C. (113 to 116.6°F.) In general, values for pantothenic acid are highest after digestion of the samples with takadiastase. Autolysis or hot water extraction (autoclaving) were substantially less effective, although considerable amounts are released by these methods. In the case of beef liver and spinach, autolytic enzymes appeared able to free essentially all of the vitamin. For assay purposes, these workers suggest employing the combined action of takadiastase and papain. They suggest that the ease with which these "combined forms" are broken down by the carbohydrate splitting preparations (some of which also possess high phosphatase activity) suggests the possible presence in tissue of certain pantothenic acid ester, amide, or glucose type linkages. Willerton and Cromwell¹¹⁹ found digestion of yeast and liver preparations with takadiastase released much pantothenic acid and brought the values obtained from these materials by microbiological methods to levels approximating those obtained by chick assays. Perhaps variable efficiency of different enzyme preparations for liberating pantothenic acid noted by different workers can be attributed to variations in the activities of the preparations. Mylase P¹²⁰ liberated more pantothenic acid than did clarase, according to Busirk and Delor.¹²¹ They used a sodium acetate buffer (pH 4.2) and incubation periods of two hours at 50 or 37°C. overnight.

It must be remembered that most commercial enzyme preparations are crude and may therefore contain significant amounts of the vitamin in question. Each lot should be standardized. Busirk and Delor noted that 75 per cent of the pantothenic acid in Mylase P could be removed by dialysis at 5°C. (41°F.) for 12 hours without impairing the enzyme activity.

The stimulatory action of a large number of compounds on *Lactobacillus casei* in the riboflavin assay of Snell and Strong were also found to give similar action when the organism was used in the pantothenic acid assay of Pennington *et al.* and of Strong, Feeney, and Earle.^{75, 86, 122}

In the medium of Strong, Feeney, and Earle, Feeney and Strong⁹⁶ reported five mg. of glutamic acid, 2.5 grams of asparagine, or 100 μ g. of glutamine were as effective in supplementing the basal medium as a quantity of norited yeast extract equivalent to 25 mg. of yeast extract. Adenine and guanine, when added to the complete medium, produced a definite inhibition at a level of 100 μ g. per tube; whereas glutamic acid, uracil, and thymine were without effect. The effects of these compounds were noted at such high concentrations the authors believed they had little

practical significance insofar as their interference in the riboflavin and pantothenic acid assays are concerned. Bauernfeind *et al.*,⁶⁰ employing the assay medium of Pennington, Snell, and Williams, were unable to observe stimulation by asparagine at levels of five mg. per tube. Pennington *et al.*⁶¹ have reported identical assay values in parallel assays using their method and that of Strong, Feeney, and Earle.

Clarke, Lechycka, and Light¹²³ have noted a substance in wheat flour producing increased acid production. The elimination of certain substances has been discussed by Bauernfeind *et al.*, and Strong and Carpenter.⁷⁵

Until recently, it has been thought that approximately 10 ml. of 0.1 N acid was the maximum capacity of most organisms of the lactic acid group. However, Wegner, Kemmerer, and Fraps⁸⁸ have shown that addition of wheat-bran concentrates to the riboflavin assay medium of Snell and Strong will allow production of twice as much acid, if the carbohydrate portion of the medium is increased sufficiently so as not to be a limiting factor. A similar observation has been reported by Clarke, Lechycka, and Light,¹²³ using rice-polishings concentrate. Addition of 400 mg. or more of rice-polishings concentrate per tube resulted in production of 20 to 23 ml. of 0.1 N acid. The ability to support this additional acid production was not affected by one treatment with Fuller's earth at pH 4. Autoclaving with sodium hydroxide at pH 12 for 30 minutes at 15 pounds destroyed the factor. About half of the activity was destroyed by takadiastase treatment at 50°C. overnight. From these observations Light and Clarke¹²⁴ studied the pantothenic acid medium of Pennington, Snell, and Williams¹¹⁰ in the hope of improving the medium with respect to its ability to support greater acid production. With increased dosage of rice-polishings concentrate, they noted a plateau of 10 ml. of 0.1 N acid was reached, but that addition of more rice concentrate resulted in a rapid increase in acidity up to 22 ml. of 0.1 N acid. This could not be explained on the basis of buffer capacity of the rice concentrate. Glucose addition to the basal medium resulted in a higher and shorter plateau level. With pure calcium pantothenate, 200 mg. of glucose per tube in the basal medium allowed a maximum of 13 ml. of 0.1 N acid in contrast to 10 ml. on the original basal medium containing 100 mg. glucose per tube, yet the rice concentrate supported 22 ml. acid production. If the basal medium was supplemented with thiamine hydrochloride, 100 μ g.; pyridoxine hydrochloride, 100 μ g.; nicotinic acid, 100 μ g.; choline chloride, 12,000 μ g.; inositol, 12,000 μ g.; biotin 2 and added riboflavin, 100 μ g. (all per tube); the maximum acid production on addition of pure calcium pantothenate was raised to 16 to 17 ml. The medium of Landy and Dicken⁶⁸ was able to support a maximum acid production of 18 ml. with additional glucose, while the plateau in the middle-dose range of rice concentrate was eliminated by the addition of asparagine. Omission of asparagine reduced the maximum acid value from 20 to 15 ml.

A medium containing casein hydrolysate and a peptone preparation supported more acid production than the medium containing casein alone.

yet the casein fraction may be eliminated if the peptone concentration is doubled. These media show a plateau at 20 ml. of 0.1 N acid, but acid production may be raised to 35 to 40 ml. if large quantities of yeast concentrate or of liver extract are tested with sufficient substrate. Pantothenic acid alone is not the stimulating factor, nor are folic acid and biotin and glutamic acid. With these latter media, satisfactory dose-response curves are obtained for pantothenic acid between 0.04 and 2.56 μ g. with acid production of 4.5 to 22.5 ml.

When the photolyzed peptone preparation of Snell and Strong is substituted for the casein in the medium and riboflavin as replaced by calcium pantothenate, preliminary studies have indicated that the medium thus modified is satisfactory for the assay for riboflavin.

The medium proposed by Light and Clarke ¹²⁴ is as follows:

Peptone preparation of Pennington, Snell, and Williams.....		40 ml.
Glucose, anhydrous.....		8 gm.
l-asparagine.....		50 mg.
l-tryptophane.....		20 mg.
l-cystine.....		20 mg.
Salt solution A.....		1 ml.
Salt solution B.....		1 ml.
Guanine hydrochloride.....		1 mg.
Adenine sulfate.....		1 mg.
Xanthine.....		1 mg.
Uracil.....		1 mg.
Thiamin hydrochloride.....		2 mg.
Riboflavin.....		2 mg.
Pyridoxine hydrochloride.....		2 mg.
Nicotinic acid.....		9 mg.
Choline chloride.....		20 mg.
Inositol.....		20 mg.
Distilled water to 100 ml.		
pH adjusted to 6.8		

Neal and Strong ¹²² expressed doubt as to the advisability of extending the titration range above 10 or 11 ml., since the large amount of acid may unfavorably influence the growth and vigor of the test organism, and the growth response is not a linear function of pantothenic acid concentrations.

BIOTIN

Biotin is one of the most powerful physiological agents known. It was discovered and later isolated in the form of the methyl ester in 1935 by Kögl.¹²⁵ Kögl and Tönnis ¹²⁶ were successful in isolating 1.1 mg. of crystalline material from 250 kg. of Chinese egg yolk, representing a yield, after 16 steps, of 1.4 per cent. Thus the original material contained only 80 mg. of biotin. These workers followed the concentration of the substance with the aid of a yeast-growth assay method, relying on a five-hour incubation period after a heavy inoculation of one mg. of yeast cells per

ml. of medium. In this case, Williams¹²⁷ has pointed out that other requirements of the test organism are supplied by the inoculum, for he and his co-workers¹²⁸ have shown that in the absence of pyridoxine, biotin is inactive.

A few years earlier Allison, Hoover, and Burk¹²⁹ reported a factor necessary for the growth of *Rhizobium* which they named "coenzyme R." A third group of investigators were attempting to isolate the factor marked for its ability in inhibiting the deleterious effects produced by feeding raw egg white. This factor was called "protective factor X" by Boas, "the protective factor against egg-white injury" by Parsons, and "vitamin H" by György. Then a remarkable merging of these independent lines of study occurred. Nilsson *et al.*¹³⁰ showed the biotin methyl ester of Kögl could replace "coenzyme R" in the metabolism of *Rhizobium*. West and Wilson,¹³¹ independently using crude preparations, suggested that biotin and coenzyme R were identical. Finally du Vigneaud and co-workers¹³² showed biotin could prevent the raw egg-white injury, thus indicating the identity of the three agents. Biotin and the raw egg-white factor, now called avidin, combine in such a way that biotin is inactive in the animal and microorganism. That different forms of biotin exist in nature has been demonstrated by Oppel¹³³ and Burke and Winzler.¹³⁴ Oppel reported 20 to 50 per cent of the yeast-growth biotin activity in urine was unaffected by addition of avidin or egg white. Burke and Winzler have found even higher amounts in urine of dog, horse, rat, cow, mouse, and sheep. In fact it was found in most all tissues and foodstuffs. The yeast activity of this avidin-uncombinable fraction, unlike biotin, is greatly reduced by boiling or autoclaving at natural pH values. This fraction is also inactive for *Rhizobium* and is designated by these writers as "miotin." A residual, comparatively heat-stable, avidin-uncombinable fraction produced by autoclaving miotin, is designated as "tiotin." A third unidentified biotin vitamer, "rhiotin," active for *Rhizobium* but not for yeast, is avidin-combinable and stable to acid and neutral autoclaving. It may be detected in human or rat urine after addition of excess avidin and precipitation of the avidin-biotin complex with acetone. Both rhiotin and miotin were inactive in the mouse, at least in doses equivalent to curative doses of biotin. *Escherichia coli* excretes large amounts of avidin-uncombinable biotin vitamers.

These vitamers are believed to be chemically closely related to biotin. Yeast growing in the presence of submaximum amounts of avidin-uncombinable biotin is able to completely convert them to a combinable form. Also, free biotin may be converted to an avidin-uncombinable form, presumably miotin. The diaminocarboxylic acid derived from biotin by

134. Burke and Winzler. 1943. Science 97, 57-60.

du Vigneaud *et al.*¹³⁵ also was converted to an avidin-combinable form.

Melville *et al.*^{135a} have recently described the preparation of desthiobiotin methyl ester from biotin methyl ester. The former compound is structurally the same as biotin except that the sulfur atom has been removed and the thioether linkage thereby replaced by hydrogen atoms. This compound exhibits full biotin activity (on a weight basis; on a molarity basis it is slightly lower because of the lower molecular weight) for *Saccharomyces cerevisiae*. Yeast growth activity can be inhibited by avidin, indicating the urea grouping is necessary for the biotin-avidin combination. Desthiobiotin is inactive for *Lactobacillus casei*.

Biotin has been shown to be a nutrilitic requirement of certain anaerobes, *Clostridium butylicum*¹³⁶ as well as *Clostridium sporogenes*.¹³⁷ It is also a growth requirement for many filamentous fungi, reviewed by Robbins and Kavanagh.⁴⁵

Lampen, Bahler, and Peterson's¹³⁸ Microbiological Method for Assaying for Biotin. These investigators described a biotin assay method employing *Clostridium butylicum*. The method was devised by Peterson, McDaniel, and McCoy¹³⁷ and also used by Lampen, Kline, and Peterson.¹³⁹ This organism on a basal medium of two per cent glucose, one per cent asparagine, and 0.11 per cent salts (K_2HPO_4 , 10 gm.; KH_2PO_4 , 10 gm.; $MgSO_4 \cdot 7H_2O$ 4 gm.; NaCl, 0.2 gm.; $MnSO_4 \cdot 4H_2O$, 0.2 gm.; $FeSO_4 \cdot 7H_2O$, 0.2 gm. per liter) requires only the addition of biotin for maximum growth.^{136, 137} The measure of growth is the turbidity as read in a photoelectric colorimeter. The organism requires anaerobic conditions for growth.

The stock culture is carried on sterile soil and a loopful is inoculated into a test tube of the basal medium containing 0.25 per cent peptone. After 18 to 20 hours' incubation, 10 ml. of this solution is centrifuged and resuspended in 10 ml. of sterile, freshly boiled water. Three drops of this washed culture are added to each tube.

Culture tubes (25 x 200 mm.) are graduated at 36 ml. for the determination. A small amount of reduced iron is placed in each tube to aid in maintaining anaerobic conditions. The biotin solution for the standard curve or an extract of the material to be assayed, dissolved in 10 ml. or less, is placed in the tube and the volume brought to 11 ml. with water.

The basal medium is prepared in such concentrations that additions of 25 ml. of it to each tube, i.e., to the 36-ml. mark, will give the desired concentration. The pH of this basal medium should be 6.5 to 6.7 before addition. The tubes are plugged and autoclaved for 30 minutes at 15 pounds pressure. They are cooled quickly and inoculated immediately. An oat-jar is prepared by filling a suitable container one-fourth full with oats and adding just enough water to cover the oats. The assay tubes are placed in the jar and a glass top sealed on with plasticine. The respiration of the oats removes the oxygen and establishes a partial pressure of carbon dioxide. The jar is then placed in the incubator for three days at 37°C. (98.6°F.).

After incubation the tubes are removed, shaken well, and their turbidity read against the uninoculated basal medium set at 100. With excess biotin a reading of 15 to 20 is obtained. One-half of the difference between the inoculated control and the maximum reading, arbitrarily taken as 20, is taken as half-maximum growth. A unit is defined as the quantity of material per milliliter of medium which is required to give half-maximum growth. This unit is 0.01 millimicrogram for pure biotin, and by comparison to the unit weight, the biotin content of crude materials may readily be calculated.

138. Lampen, Bahler, and Peterson. 1942. J. Nutr. 23, 11-21.

139. Lampen, Kline, and Peterson. 1941. J. Biol. Chem. 140, lxxiv.

The authors noted that considerable variation exists between duplicate tubes, even on pure biotin, and place the accuracy of the method at ± 20 per cent.

If the pH of the medium is brought to 6.3 before autoclaving, a flocculent precipitate appears during autoclaving and incubation. Consequently, the medium must be adjusted to pH 6.6 to 6.7. Though use of the oat jar for maintaining anaerobic conditions is cumbersome, reduced iron, sodium thioglycolate, gave unsatisfactory results in that many tubes failed to initiate growth. Addition of agar, cystine or sodium hydrosulfite, was also unsatisfactory. Lampen, Kline, and Peterson have noted that irregularities may occur owing to variations in reagents, vigor of culture, anaerobic conditions, and perhaps other factors.

Snell, Eakin, and Williams'¹⁴⁰ **Yeast Method for Assaying for Biotin.** They reported a yeast-growth method for assaying for biotin. The test organism is a certain strain of *Saccharomyces cerevisiae*, designated by them as the "F.B." strain, which they isolated from Fleischmann's compressed yeast. This strain has been deposited with the American Type Culture Collection. The basal medium contains:

Sucrose.....	20.0 gm.
Ammonium sulfate.....	3.0 gm.
Potassium dihydrogen phosphate.....	2.0 gm.
Magnesium sulfate heptahydrate.....	0.25 gm.
Calcium chloride dihydrate.....	0.25 gm.
Boric acid.....	1.0 mg.
Zinc sulfate.....	1.0 mg.
Manganese chloride.....	1.0 mg.
Thallium chloride.....	1.0 mg.
Ferric chloride.....	0.5 mg.
Cupric sulfate pentahydrate.....	0.1 mg.
Potassium iodide.....	0.1 mg.
l-Aspartic acid.....	0.1 gm.
Inositol.....	5.0 mg.
β -alanine.....	0.5 mg.
Thiamine.....	20.0 μ g.
Pyridoxine.....	20.0 μ g.
Distilled water to 1 liter	

Addenda to the basal medium are dissolved in two ml. of water in 50-ml. Erlenmeyer flasks and sterilized by steaming for five minutes. After cooling, 10 ml. of the previously sterilized basal medium containing 0.02 mg. of suspended yeast are pipetted into each flask which is set unstoppered and without agitation in an incubator at 30°C. (86°F.) for the growth period of approximately 16 hours. Very clean glassware is essential for proper results. The authors have noted the method is sensitive to the presence of toxic substances in tissue extracts or on the glassware itself.

At the end of the growth period the yeast suspension is diluted with 10 ml. of saturated aqueous thymol and shaken mechanically for three to five minutes. The amount of yeast present is determined by use of a photoelectric colorimeter. The same instrument is used to gauge the seeding in the basal medium at the start, the concentration being determined indirectly from a heavy suspension from which the proper dilution is taken.

Blank cultures (no addenda) and cultures containing known amounts of biotin (0.000025 to 0.00025 μ g.) are run simultaneously with the unknowns, and the amounts of biotin in the unknown samples are read off the standard curve, in which the galvanometer readings are plotted against the known amounts of biotin added.

The above procedure has been slightly modified so that assays are carried out in bacteriological test tubes which are conveniently supported by a wire or metal rack which may be autoclaved. The standard biotin solutions and solutions for analysis are added to the tubes. Standard tubes containing 0, 10, 20, 30, 50, 70, and 100 m μ g. of

140. Snell, Eakin, and Williams. 1940. Amer. Chem. Soc. J. 62, 175-178; Univ. of Texas. Pub. 4137, 18-21.

biotin are satisfactory to establish the standard curve. Various amounts of practically clear tissue extracts may be selected by preliminary experiments or estimates to contain approximately 10 to 80 $\mu\text{g.}$ of biotin. Volumes up to one ml. may be used. The contents of all tubes are then diluted, if necessary, to one ml. with water. Then five ml. of previously sterilized basal medium, containing 0.2 mg. per 100 ml. of the test organism, are added to each tube. The open tubes are then placed in the 30°C. incubator for a growth period of approximately 16 hours.

For establishing the standard curve, either free biotin or biotin methyl ester may be used, since the yeast is able to utilize either with equal efficiency.

Du Vigneaud *et al.*¹⁴¹ have employed the Snell, Eakin, and Williams' yeast method, with certain modifications, for following the concentration and determination of activities of certain derivatives of biotin. The Fleischmann strain 139 *Saccharomyces cerevisiae* was used and turbidity measurements were made with a Klett-Summerson photoelectric colorimeter with a blue filter (Klett No. 42). This instrument is equipped with a logarithmic scale so that turbidity readings observed are a linear function of yeast growth. By plotting the turbidity readings against the logarithms of the concentrations of assay material, an S-shaped curve is outlined.

Snell *et al.* used several methods for preparing samples for assay. Clear aqueous extracts were obtained by autoclaving the finely ground material for 10 minutes at 15 pounds pressure in a large volume of water. If necessary, the extract was clarified by filtering with filter-cel. Casein samples were hydrolyzed with sulfuric acid and the sulfate ion removed with barium hydroxide. Liver tissue was allowed to autolyze before assay. A more complete discussion is given below.

Hertz's¹⁴² Modification of the Snell, Eakin, and Williams' Microbiological Method for Assaying Biotin. A modification of the Snell, Eakin, and Williams¹⁴⁰ yeast-growth method for assaying for biotin has been proposed by Hertz through the addition of a biotin-free casein hydrolysate. Elimination of nonspecific stimulation of yeast growth is claimed, particularly as encountered in human and canine urine samples. The technic of the assay is somewhat different from that employed by Snell *et al.*

The medium requires the following ingredients of highest purity:

Sucrose.....	34.0	gm.
Ammonium sulfate (anhydrous).....	5.0	gm.
KH ₂ PO ₄	4.0	gm.
d-l-aspartic acid.....	170.0	mg.
MgSO ₄	450.0	mg.
CaCl ₂	450.0	mg.
Mineral salts (cf. Snell <i>et al.</i>).....	0.18	mg. equivalent
Inositol.....	9.0	mg.
10% biotin-free casein hydrolysate.....	1.0	gm. equivalent (pH 3.0)
Thiamin.....	1.0	mg.
Pyridoxin.....	1.0	mg.
Calcium pantothenate.....	0.5	mg.
Distilled water to 1 liter		

The pH of this preparation without adjustment is usually between 3.8 and 4. These materials are added successively. Gentle warming may be required to dissolve completely. The medium may be stored in the refrigerator for at least three weeks without deterioration.

141. Du Vigneaud, Hofmann, Melville, and György. 1941. *J. Biol. Chem.* 140, 643-651.

142. Hertz. 1943. *Soc. Expt. Biol. and Med. Proc.* 52, 15-17.

The test is carried out in previously calibrated photometric tubes measuring 180 x 20 mm. In each culture tube five ml. of the above medium are added to variable proportions of the test materials and the final volume in all tubes is adjusted to 10 ml. with distilled water.

A stock culture of *Saccharomyces cerevisiae* (No. 139, obtained from the Fleischmann Company) is carried at room temperature on Sabouraud's agar, transfers being made at least every three days. The test inoculum is prepared from a 24-hour culture grown at 37°C. in test medium to which has been added an effective quantity of biotin. This culture is washed twice with normal saline and its final concentration is adjusted turbidimetrically so that the 0.5 ml. used for each test culture contains approximately 0.05 mg. of suspended cells.

The test cultures are incubated without plugs for 18 to 22 hours at 37°C. in a forced-draft incubator.

Assay values are determined turbidimetrically in relation to a standard curve obtained for each run in duplicate with crystalline biotin dilutions ranging in content from 1×10^{-4} to 5×10^{-4} μ g. per culture.

Samples may be prepared either by hot water or acid extraction, depending on the nature of the material to be tested. Only water-clear preparations may be employed.

The following compounds were found to have no effect on the assay results: pimelic acid, nicotinic acid, riboflavin, adenine, guanine, uracil, choline, and ethanolamine.

Considerable care must be taken to keep the age and preparation of the inoculum quite constant. Variations in this regard will alter the results from day to day.

Another yeast-growth method has been reported by Atkin, Schultz, Williams, and Frey.¹⁰⁴ This method is discussed in detail in the section on pyridoxin below. West and Woglam¹⁴³ used *Rhizobium trifolii* based on the medium used by West and Wilson.¹⁴⁴ Robbins and Schmidt¹⁴⁵ have suggested a biotin assay based on the weight of mycelium of *Ashbya gossypii* produced in 15 to 20 days' growth on a basal medium of inorganic salts, sucrose, inositol, and thiamine.

Biotin is a growth factor for *Lactobacillus casei* ϵ , and assay methods using this organism have been proposed. One by Landy and Dicken⁶⁵ will be discussed in detail in a subsequent section of this chapter.

Shull, Hutchings, and Peterson's¹⁴⁶ Method for Assaying for Biotin. The first method employing *Lactobacillus casei* ϵ for the assay of biotin was that of Shull, Hutchings, and Peterson. Its advantages over the yeast methods lies in the fact that lactic acid production may be used to gauge the response of the assay organism and thus overcomes the difficulties of colored and turbid solutions encountered when turbidimetric determinations of yeast growth are used.

Stock cultures of *Lactobacillus casei* ϵ are carried as stabs in yeast extract-glucose agar in a refrigerator until used. The inoculum for the assay is started two days before the assay is to be set up. A transfer is made from a stab culture to a tube of liquid medium (10 ml.) containing 0.5 per cent Difco yeast extract, 0.6 per cent sodium acetate, 0.5 per cent glucose, and 0.05 ml. of mineral salts Solutions A and B per tube. The culture is incubated at 37°C. for 24 hours and then transferred to the sterile biotin-free basal medium described below. A two-per cent inoculum is used for the transfer, i.e., 0.2 ml. per 10 ml. of the biotin-free basal medium. This inoculum supplies sufficient biotin for a good growth of the organism. This culture is incubated for 15 to 20 hours at 37°C. One drop (0.05 ml.) of this suspension is used to inoculate each tube in the assay series.

143. West and Woglam. 1941. Science 93, 525.

144. West and Wilson. 1940. Enzymologia 8, 152.

145. Robbins and Schmidt. 1939. Torrey Bot. Club Bull. 66, 139-150.

146. Shull, Hutchings, and Peterson. 1942. J. Biol. Chem. 142, 913-920.

Shull and Peterson ^{146a} found the above inoculum was satisfactory when the drop size was constant. An increased titer always resulted when more than one drop of the heavy inoculum was added per tube. Another procedure has been devised which gives more consistent results and is independent of the size of inoculum (one to three drops). Transfer the stock culture to 10 ml. of yeast extract medium, described above, 24 hours before the assay is set up. After 20 to 30 hours' incubation at 37°C., the cells are centrifuged and resuspended in 10 ml. distilled water. One drop (.05 ml.) of the resuspended cells is transferred to 10 ml. sterile water, and one drop of this dilute suspension is used in each assay tube for inoculum.

The final composition of the basal medium is as follows:

Peroxide-treated hydrolyzed casein.....	0.50 per cent
Peroxide-treated norited yeast filtrate.....	0.15 per cent
Tryptophane.....	0.0075 per cent
Cystine.....	0.01 per cent
Asparagine.....	0.02 per cent
Glucose.....	1.0 per cent
Sodium acetate.....	1.0 per cent
Pyridoxine.....	0.02 mg. per cent
Pantothenic acid.....	0.02 mg. per cent
Riboflavin.....	0.01 mg. per cent
Nicotinic acid.....	0.10 mg. per cent
p-Aminobenzoic acid.....	0.01 mg. per cent
Adenine.....	1.00 mg. per cent
Guanine.....	1.00 mg. per cent
Mineral salts, 0.5 ml. each, Solutions A and B in 100 ml. of medium.	

For assay purposes the medium is prepared in twice this concentration for dispensing into the assay tubes.

CONSTITUENTS OF THE MEDIUM

Peroxide-Treated Hydrolyzed Casein: One hundred grams of vitamin-free casein with 375 ml. of water and 125 ml. of concentrated sulfuric acid are hydrolyzed for 15 hours at 120°C.(248°F.) in an autoclave. The 15-hour treatment hydrolyzes the casein sufficiently for the organism to utilize the hydrolyzate, but it is not long enough to destroy completely the "eluate factor" required by *Lactobacillus casei* ^ε.¹⁴⁷ Six hundred and forty grams of Ba(OH)₂·8H₂O suspended in 400 ml. of boiling water are added to the hydrolyzate and the precipitated barium sulfate is filtered off with filter-cel. The filter cake is removed and thoroughly broken up in 500 ml. of hot water. The washings from the filter cake are added to the main filtrate. The pH of the filtrate is adjusted to 3 with sodium hydroxide. The solution is then diluted to 1,500 ml. with water and 15 ml. of Superoxol¹⁴⁸ are added. The solution is thoroughly stirred and allowed to stand for 24 hours at room temperature, 25 to 32°C.(77 to 89.6°F.). The pH is then adjusted to 7 with sodium hydroxide and one per cent of powdered manganese dioxide is added. The solution is mechanically stirred until no more oxygen is evolved (about 15 minutes) and filtered with suction. The filtrate is then diluted to 2,000 ml. with water.

Peroxide-Treated Norite Yeast Filtrate: Twenty grams of Bacto-yeast extract are dissolved in one liter of distilled water and the pH is adjusted to 2 with concentrated

148. Superoxol, 30 per cent hydrogen peroxide. Merck & Co., Inc., Rahway, N. J.

sulfuric acid. Four grams of norite A are added, the adsorption is carried out at 56 to 60°C. (132.8 to 140°F.) with mechanical stirring for half an hour. The norite is removed by filtration with the aid of filter-cel. The pH of the filtrate is adjusted to 3 with 10 N sodium hydroxide and the volume is made up to 3,000 ml. with water. Thirteen ml. of Superoxol are added, and the solution is allowed to stand at room temperature for 24 hours. The pH is then adjusted to 7 with 10 N NaOH, and 13 grams of powdered manganese dioxide are added. The solution is mechanically stirred until the evolution of oxygen ceases. The manganese dioxide is removed by vacuum filtration. The final volume should be about 1,325 ml.

Shull and Peterson^{146a} have noted at times poor growth in the above medium even in the presence of excess biotin. This was attributed to a low level of folic acid ("eluate factor") supplied by the yeast extract preparation. By the above procedure the removal of biotin often brings the folic acid to a critical level. A new procedure for its preparation has given satisfactory assays:

Twenty grams of Bacto yeast-extract are dissolved in a liter of distilled water and adjusted to pH 2 with sulfuric acid. Four grams Norite A are added, the absorption carried out at 55 to 60°C. with mechanical stirring for 30 minutes. The norite is filtered off and the filtrate is saved for later use. The norite is eluted with 200 ml. 50-per cent ethanol at room temperature for 15 minutes. This eluate, containing a part of the biotin of the original material is discarded and the norite eluted a second time with 200 ml. solution containing 10 parts ammonium hydroxide (28 per cent), 50 parts 95 per cent ethanol and 40 parts distilled water at 55 to 60°C. The extracted norite is discarded and the eluate is distilled *in vacuo* to remove the ethanol and ammonia. The eluate is then diluted to 200 ml. and adjusted to pH 3. Ten grams Super Filtrol are added and the mixture is stirred for 15 minutes at room temperature. The Super Filtrol adsorbs the eluate factor but leaves most of the biotin in the filtrate. After filtration, the Super Filtrol is eluted with 200 ml. of the ammoniacal ethanol solution, described above, for 15 minutes at room temperature. This eluate is distilled *in vacuo* until the ethanol and ammonia are removed. It is then added to the norite-yeast filtrate from the first operation and the combined solution is made to 1,300 ml. The solution is adjusted to pH 3 and 13 ml. superoxol (30 per cent hydrogen peroxide) are added to oxidize the small amount of biotin contained in the solution. The solution is allowed to stand for 24 hours at room temperature, after which the pH is adjusted to 7 and 15 mg. of MnO₂ are added with stirring. When evolution of oxygen has ceased the solution is filtered and is ready for use in the assay.

Vitamin Solution: Two hundred ml. of stock solution containing 100 µg. of pyridoxine, 100 µg. of calcium pantothenate, 50 µg. of riboflavin, 500 µg. of nicotinic acid, and 50 µg. of p-aminobenzoic acid per ml. is prepared. This solution is stored with added toluene in a refrigerator.

Adenine-Guanine-Cystine Solution: One liter of a stock solution containing 500 µg. per ml. of adenine, 500 µg. per ml. of guanine, and one mg. per ml. of cystine is prepared by dissolving these compounds in water with the addition of the least amount of sulfuric acid to effect solution.

Mineral Salt Solutions: Solutions A and B are the same as employed in the Snell and Strong riboflavin procedures, and the two pantothenic acid procedures described previously in this chapter.

The basal medium is prepared double strength, and after adjusting the pH to 5.6, five ml. are dispensed into test tubes. Solutions to be assayed are added to one set of tubes. Biotin for the standard curve is added to the other set. The final volume in each tube is made up to 10 ml. with distilled water. The tubes are plugged, with cotton and autoclaved for 15 minutes at 120°C. After cooling, the tubes are inoculated with one drop of inoculum as described above. The tubes are then incubated for three days at 37°C. After incubation the contents of each tube are titrated with 0.1 N NaOH. Brom thymol blue may be used as an indicator though phenol red gives a better end point.

Lactobacillus casei is unable to utilize the methyl ester of biotin, consequently the biotin to be used for this assay should be in the form of the free acid. By hydrolyz-

ing the methyl ester as described by du Vigneaud *et al.*¹⁴⁹ the full activity of the biotin may be restored. The range of biotin used for calibration of the standard curve is from 40 to 1,000 m μ g. (.04 to 1.0 μ g.) per tube. The curve is then constructed by plotting the milliliters of 0.1 N alkali used in the titration against the amounts of biotin per tube. The extremities of the curve do not give valid results, so samples should be dilute so that their titers do not come at these portions of the curve.

It has been shown by Nielsen, Shull, and Peterson¹⁵⁰ that biotin inactivated by hydrogen peroxide treatment, as in the *Lactobacillus casei* assay of Shull, Hutchings, and Peterson,¹⁴⁶ while inactive for *Lactobacillus casei* and the rat, still has marked potency for yeast apparently owing to resynthesis of the vitamin. In the assay of biological materials for biotin oxidizing conditions should be avoided in the preparation of the sample. Intestinal synthesis of biotin in rats varies with different rations, and becomes very low when sulfaguanidine is incorporated in the diet. Stokes and Gunness^{150a} reported *Lactobacillus casei* to be capable of utilizing biotin methyl ester, though at a somewhat slower rate than the free acid.

It has been shown repeatedly that the biotin contents of certain products as determined by microbiological methods depends on the method of preparation of the samples. Snell, Eakin, and Williams¹⁴⁰ showed the existence of "bound" biotin in liver tissue, a form of biotin unavailable for the test organism, which may be liberated by autolysis. Assays of egg-yolk extracts were not increased by autolysis. Peterson and co-workers¹³⁷ noted that strong acid hydrolysis would release bound biotin, though prolonged acid hydrolysis may destroy some biotin in certain tissues. Biotin in fruit and grasses appears to occur free, that of grains, nuts, and vegetables is partially bound, and that of yeast and animal tissues is mainly in the bound form. Landy and Dicken¹⁵¹ preferred acid hydrolysis because of the danger of bacterial production of biotin during autolysis. Lampen, Bahler, and Peterson¹⁵² have compared various biotin extraction procedures. Liver was extracted with 4 N and 7 N sulfuric acid by autoclaving for one hour, with no destruction noted after four hours. With yeast one hour with 4 N sulfuric acid gave maximum values, but after two to three hours some destruction was noted. Autolysis liberated biotin more readily from yeast than from liver. Autolysis for 24 hours, either with toluene or toluene-chloroform, released 80 to 90 per cent of the biotin of yeast, with maximum liberation in six days. No destruction occurred during three weeks of autolysis. No inhibition by chloroform of the liberation of biotin during autolysis, as experienced by György,¹⁵³ was noted. Lampen *et al.*¹⁵² found biotin liberation from liver by autolysis was slow and incomplete, never more than 30 per cent becoming available. Treatment with pepsin for seven days at 50°C. (122°F.) was incomplete. Hydrolysis with trypsin for three hours at 50°C. completely liberated biotin. Boiling the liver to destroy enzyme activity lowered the yield of biotin as

153. György. 1939. J. Biol. Chem. 131, 733-744.

did using lower temperatures. For routine assays of materials known to contain the bound forms of biotin, Lampen *et al.* homogenized samples and hydrolyzed them in 2 N sulfuric acid for two hours, followed by removal of the sulfate with barium hydroxide. Hydrolysis in milk for one hour with 1 N sulfuric acid gave maximum values. A simpler method, giving equal values, involved diluting five ml. of milk to 50 ml. with an acetate buffer of pH 4.6, filtering off the casein, and assaying the filtrate.

Biotin in green plants and vegetables exists in a free, water-soluble form available for the test organism. Some destruction was noted with tomatoes. Biotin in fruits is also water soluble. Soybeans, navy beans, and rye appeared to contain bound biotin, whereas corn and barley did not. The values for wheat were contradictory. The biotin in nuts is firmly bound, requiring 2 N or 4 N sulfuric acid for its liberation, though in some instances destruction was noted when the stronger acid was used.

That large amounts of biotin are released by autolysis of tissue was first reported by György¹⁵³ and confirmed by Snell, Eakin, and Williams.¹⁴⁰ Thompson, Eakin, and Williams¹⁵⁴ noted that neither enzyme hydrolyses, autolysis, or a mixture of clarase and caroid were as efficient in liberating bound biotin as acid hydrolysis. Two or more hours of autoclaving in 6 N sulfuric acid yielded maximum values, though 6 N hydrochloric acid was somewhat more effective. Some destruction of biotin was noted after prolonged hydrolysis with strong acids. Cheldelin¹⁵⁵ used enzyme liberation as a routine procedure. Papain was most effective with other proteolytic enzymes being more effective than carbohydrases. The effectiveness of autolysis varied greatly with different tissues. The only protein-biotin complex so far discovered is that with avidin which is not attacked by enzymes of the digestive tract. Manure samples showed increased biotin assay after acid hydrolysis.¹⁵⁶

AVIDIN

Feeding of a nutritionally adequate diet containing raw egg white causes a type of injury in rats and chicks commonly called "raw egg white injury." Replacement of the raw egg white with cooked egg white reverses or prevents the injury. Tissues of chicks maintained on the former diet were found to be deficient in biotin.¹⁵⁷ It was concluded that the injury was not due to any direct toxin, but rather was produced indirectly by making the biotin of the diet unavailable to the animal. Eakin, Snell, and Williams¹⁵⁸ successfully demonstrated *in vitro* inactivation of biotin and showed that a protein constituent of unheated egg white formed a stable complex with biotin which could not be recovered by dialysis, and that the combination occurs stoichiometrically. Yeast, *Rhizobium*, and other microorganisms are also unable to utilize biotin in such a complex. The protein responsible for the complex is called "avidin." It is not a

vitamin; perhaps the term "anti-vitamin" is appropriate. Eakin and colleagues concentrated the protein and Pennington, Snell, and Eakin¹⁵⁹ later crystallized it. After concentration it was soluble in half-saturated ammonium sulfate. When saturated ammonium sulfate was added to incipient precipitation, the precipitate removed by centrifugation, and the clear supernatant solution chilled in a refrigerator, needle-like crystals formed in an hour. Slow crystallization resulted in large plate-like crystals. Both forms retained high activity on repeated crystallizations, though some potency was lost during the processes. Crystals in presence of the mother liquor for three weeks in a refrigerator lost 75 per cent of their activity, though dry crystals at room temperature retained full potency after three months. The crystalline material gave a positive Molisch test, indicating the substance may be a protein with a large carbohydrate moiety.

Eakin, Snell, and Williams'¹⁵⁸ **Avidin Assay Method.** A modification of the yeast-growth method for assaying biotin¹⁴⁰ has been used in the assay of avidin.¹⁵⁹ The test is set up in duplicate and the assay of one set is carried out without heat sterilization. The duplicate set is sterilized in the customary manner by steaming for 15 minutes at 100°C. (212°F.), thus permanently denaturing the avidin and releasing biotin from the complex. The difference in biotin content between the heated and unheated aliquots gives a direct measure of the amount of biotin-inactivating protein present.

Cultures containing known amounts of biotin are run with each test to give the values for the points of the standard curve. A solution containing the active protein is diluted to such a volume that it contains 0.002 to 0.006 units per ml. A 0.1-ml. aliquot of the standard biotin solution is added to 0.1 mg. of each protein sample; these samples are incubated for 30 minutes at room temperature and then diluted to 10 ml. Aliquots of 0.2, 0.4, and 0.8 ml., diluted to one ml. with water, are used for both the heated and unheated assays. One of the duplicate sets of standard and sample tubes is sterilized by steaming for 15 minutes at 100°C.

The medium and yeast used are those described in the biotin assay method of Snell, Eakin, and Williams.¹⁴⁰ The medium is sterilized, cooled, and seeded with an aliquot of yeast suspension to contain approximately 0.002 mg. of moist yeast per ml. of medium. After the yeast is thoroughly suspended, five ml. of the inoculated medium are added to each tube, and the cultures are incubated without agitation at 30°C. (86°F.) for 16 to 18 hours. The yeast growth is then determined turbidimetrically. The amounts of biotin in the aliquots tested are read from the curves obtained by plotting the readings given by the biotin standards. The difference in biotin values (in micrograms of biotin) found for a heated and unheated aliquot of a sample gives the units of avidin in that aliquot.

A unit of avidin is the amount of concentrate of sample capable of inactivating one μ g. of biotin. Raw egg white usually varies from 0.4 to 0.6 units per ml.

That there are different types of biotin-avidin complexes has recently been shown by Burke and Winzler.¹⁶⁰

INOSITOL

Meso-inositol was the first pure substance to be isolated from "bios"¹⁶¹ and shown to be part of the yeast-growth stimulatory activity. It has been shown to serve as a yeast-growth factor by numerous workers. Janssen¹⁶² showed it to be indispensable for Wildier's yeast, and Williams,

162. Janssen. 1935. Arch. Internatl. de Physiol. 40, 975.

Eakin, and Snell ¹⁶³ reported it to be required by other strains of *Saccharomyces cerevisiae*.

Demonstration of vitamin activity of meso-inositol was the result of work of Woolley ¹⁶⁴ who showed it to cure alopecia in rats which had been fed on a diet devoid of this factor.

The salient characteristics of inositol were given by Waisman ³¹ as follows:

Inositol ($C_6H_{12}O_6$, an H—OH group on every carbon link of the hydrogenated benzene ring).

Properties: Sugarlike compound, very soluble in water.

Function: Unknown. Importance in nutrition has been shown through rat and mice experiments. Some evidence for lipotropic action.

Distribution: Exists in all grains, heart muscle, and yeast.

Lack of information concerning the activity of this compound may be partially accounted for by the lack of specific satisfactory methods for its determination. Eastcott employed a yeast-growth method but its application was limited. Kögl and Hasselt ¹⁶⁵ also used the same principle. Winter ¹⁶⁶ and Young ¹⁶⁷ summarized various procedures. These relied wholly or in part on isolation of the compound. Such procedures require large samples and are laborious and time-consuming. Woolley ¹⁶⁴ showed that for liver extracts, at least, these methods are not quantitative. As more yeast-growth factors have been isolated and identified, specific inositol methods based on yeast growth have been developed. One of the first satisfactory methods was proposed by Williams, Stout, Mitchell, and McMahon.¹⁶⁸

Williams, Stout, Mitchell, and McMahon's ¹⁶⁸ Method for Microbiological Assay for Inositol. This method employed the Gebrüder Mayer strain of *Saccharomyces cereivisiae* (Amer. Type Culture Collection). The inositol-free medium is as follows:

Sucrose.....	20.0 gm.
Potassium dihydrogen phosphate.....	2.0 gm.
Ammonium sulfate.....	3.0 gm.
L-Asparagine.....	3.0 gm.
Calcium chloride.....	0.25 gm.
Magnesium sulfate.....	0.25 gm.
Boric acid, zinc sulfate, thallium chloride, manganese sulfate.....	1.0 mg. each
Ferric chloride.....	0.5 mg.
Copper sulfate.....	0.1 mg.
Potassium iodide.....	0.1 mg.
Vitamin-free hydrolyzed casein.....	0.2 gm.
Biotin.....	0.2 µg.
Calcium pantothenate.....	300.0 µg.
Folic acid.....	0.5 µg.
Thiamine hydrochloride.....	20.0 µg.
Pyridoxine hydrochloride.....	20.0 µg.
Distilled water to 1 liter

Calf's Liver Supplement for Method A of Inositol Test: This supplement is made up by preparing an extract of calf's liver in the same way as indicated for the preparation of autolysates, except that the concentration is equivalent to 75 mg. of tissue per ml. instead of 25 mg. per ml. The extract is put in plugged tubes, autoclaved 15 minutes at 15 pounds pressure, and stored in a cool place. This extract should be assayed, and if it contains much over 500 micrograms of inositol per gram of liver it should not be used.

Tissue autolysates are prepared by homogenizing, according to the method of Potter and Elvehjem,¹⁰⁸ and allowing the sample to autolyze under benzene for 24 hours at 37°C. The autolyzed tissue is then washed into 0.1 N acetic acid and steamed in an autoclave for 30 minutes to insure removal of the benzene and cessation of enzyme action.

Method A: Assays are carried out in bacteriological test tubes. These are conveniently supported in a wire or metal rack which may be steamed. Standard tubes contain 0, 0.16, 0.32, 0.48, 0.64, and 0.80 μ g. of inositol in a volume of from 0 to 0.1 ml. Tissue extracts are diluted so that volumes of 0.01 ml. to 0.1 ml. contain from 0.1 to 0.8 μ g. of inositol. The standard and sample dilutions are pipetted with a syringe-type micro-pipette.

Enough basal medium to supply two ml. per tube for all the tubes in the test is placed in one flask, and about 10 to 15 ml. of medium is put in a small flask to be used for seeding. One ml. of a calf's liver autolysate (equivalent to 75 mg. of calf's liver) is added to each 100 ml. of basal medium. This supplement provides certain yeast-growth substances which are as yet unknown but does not contain enough inositol to interfere with the test. The medium, racks of tubes, a 10-ml. graduated pipette, and a one-ml. graduated pipette are steamed in the autoclave at 100°C. for 10 minutes and then cooled to room temperature. The small flask of medium is seeded from an agar slant. The yeast is suspended uniformly and the number of milligrams of moist yeast cells per milliliter of solution is determined by use of a photoelectric colorimeter and the appropriate calibration curve. By calculation, enough of this suspension is taken to seed the larger amount of medium with 0.15 mg. of moist yeast cells per 100 ml. of solution. After introduction of the yeast suspension and thorough shaking, two ml. of the medium are added to each tube in the test. The tubes are placed in a 30°C. water bath for growth periods of 15 hours.

The turbidity produced in the various tubes after 15 hours incubation is quantitatively determined in a photoelectric colorimeter. When the tubes are removed from the incubator they are placed in the refrigerator for 10 minutes to slow down the rate of growth of the test organism. They are then removed and diluted with five ml. of saturated chlorothymol solution. If the test consists of only a few tubes, only the dilution with chlorothymol is necessary. Before reading in the colorimeter the tubes are shaken vigorously, then allowed to stand a few moments to allow the air bubbles to rise and break, suspended again by less vigorous shaking, and read.

A standard curve (response to pure inositol) is obtained with each set of assays. The samples for assay are dosed at increasing levels of concentration and the inositol content of each tube is read from the standard curve. Usually three or more concordant results at different dosage levels are averaged to obtain the final curve. At random, selection of assay values obtained from single cultures showed a percentage deviation from the mean of 3.3 per cent.

Method B: Autolysates from some tissues seem to contain an especially high concentration of inhibitory or stimulatory materials that cause varying assay values or poor recoveries of added inositol. In these cases Method B is employed. The procedure is the same as for Method A except that instead of adding the liver-extract supplement, an autolysate of the tissue being tested is added. The amount of tissue autolysate added depends on the inositol content of the tissues. For tissues containing about 500 μ g. of inositol per gram of moist tissue, an amount of autolysate equivalent to one mg. of moist tissue is added for each milliliter of basal medium used in the test. If the amount of inositol in the tissue is greater than 500 μ g. per gram, a proportionately smaller amount of autolysate is added (and vice versa).

Woolley's¹⁶⁹ Yeast Method for Assaying for Inositol. Vitamin-free casein was hydrolyzed by heating in an autoclave at 15 pounds pressure for 16 hours with 7 N sulfuric acid and the acid was removed from the hydrolysate with barium hydroxide. The filtrate from the barium sulfate was adjusted to pH 6 with sodium hydroxide. An aliquot of this hydrolysate equivalent to 2.5 grams of casein was mixed with 100 grams of glucose, 8.3 grams of ammonium nitrate, 4.2 grams of potassium dihydrogen phosphate, 2.1 grams of magnesium sulfate, 0.7 gram of calcium chloride, and approximately 300 ml. of water and heated in an autoclave (15 pounds for 15 minutes). The precipitate which formed was removed and to the filtrate was added the nondialyzable portion of 10 grams of rice-bran extract (Vitab, National Oil Products Company). This latter preparation was made by dissolving rice-bran extract in water and dialyzing against running water for 48 hours. The mixture of growth factors described below was added, followed by the concentrate of Bios II, described by Lucas,¹⁷⁰ equivalent to 10 grams of malt sprouts. The volume was then adjusted to 500 ml. and the solution was preserved with toluene. The growth-factor mixture was composed of 0.5 mg. of thiamine, 0.5 mg. of riboflavin, 0.5 mg. of pyridoxine, 1 mg. of nicotinic acid, 2.5 mg. of choline chloride, 1 mg. of pimelic acid, 5 mg. of asparagine, 0.05 mg. of biotin, 0.5 mg. of sodium pantothenate, 2.5 mg. of uracil, and 2.5 mg. of adenine. Biotin was supplied as a concentrate which contained one per cent biotin, prepared according to the method of Woolley, McDaniel, and Peterson.¹⁷¹ Crystalline biotin was substituted without affecting the results.

*Preparation of Bios II Concentrate According to Lucas.*¹⁷⁰ Nine hundred seventy-five ml. of water are brought to boiling and 150 grams of dried rootlets of sprouted malt (combings) are added with stirring. The temperature is held between 80 and 85°C. (176 and 185°F.) for 10 to 15 minutes, during which time the roots become swollen. The whole is then transferred to a press and squeezed as dry as possible, yielding 650 to 700 ml. of a light brown infusion. This is concentrated by boiling *in vacuo* at a temperature of 35 to 50°C. (95 to 122°F.) to one-quarter of its volume. To the concentrate is added twice its volume of 95-per cent alcohol, stirring meanwhile. A voluminous, stringy precipitate is removed by filtration, leaving a clear, reddish filtrate which contains the whole bios but only 60 per cent of the solids of the original infusion.

The alcoholic filtrate is concentrated *in vacuo* (35 to 50°C.) to one-tenth the volume of the original infusion. To this "alcoholic concentrate" is added a hot, saturated, aqueous solution of barium hydroxide in quantity determined as explained below. A slimy precipitate is formed which is not removed and a strong smell of ammonia or amines is given off. Barium hydroxide is added until the clear supernatant liquid no longer gives an immediate precipitate when a few drops of concentrated baryta water are added. Between 30 and 60 grams of $\text{Ba}(\text{OH})_2 \cdot 7\text{H}_2\text{O}$ per liter of infusion are required. The precipitate, after it has been filtered off, is washed with dilute alcohol (two volumes of 95-per cent to one volume of water), and the filtrate and washings are combined for extraction of Bios II. This "Bios II liquor" is saturated with carbon dioxide to remove the barium ions, the carbon dioxide being removed by boiling *in vacuo* and the precipitate filtered off. Any excess barium must be removed with sulfuric acid. The filtrate is evaporated *in vacuo* at as low temperature as possible until large bubbles are formed which completely fill the vessel; this occurs when the volume has been reduced to one-tenth to one-fifteenth that of the original infusion. Acetone is added until no further precipitation occurs; at first it is a milky precipitate disappearing on shaking; on further addition of acetone a heavy, red, oily liquid separates and later a yellowish gum ("acetone precipitate") forms which adheres to the walls of the vessel. From 0.8 to 1.5 volumes of acetone are required. The precipitate is removed, washed with acetone, and the washings added to the filtrate which is concentrated *in vacuo* until the reddish-yellow residue is almost the consistency of a gum. This is washed with warm acetone to dissolve Bios II (acetone equal to about

169. Woolley. 1941. J. Biol. Chem. 140, 453-459.

171. Woolley *et al.* 1939. J. Biol. Chem. 131, 381-385.

half the original volume of solution is used). The acetone is evaporated *in vacuo* leaving a thick, reddish liquid, which is diluted with water to the original volume of the infusion. It contains 80 to 90 per cent of the Bios II of the original extract.

Woolley employed the Hansen No. 1 strain of Toronto yeast (*Saccharomyces cerevisiae*) which was maintained on slants of the basal medium plus an aqueous extract of malt sprouts (extract of 10 grams of malt sprouts per 100 ml. of medium). The organisms were transferred to liquid medium of the same composition and grown for 24 hours at 30°C. (86°F.). The cells were then collected by centrifugation and washed three times with sterile phosphate buffer. They were then suspended in a volume of buffer 20 times that of the original culture. One drop (0.05 ml.) of this suspension was used for inoculation of each flask. This inoculum introduced about 70,000 cells whose dry weight was approximately seven μg .

Preparation of Samples for Assay: A quantity of material expected to contain approximately 20 μg . of inositol was refluxed in 18 per cent hydrochloric acid for six hours. Many times it was convenient to use larger samples and to conduct the final estimation with aliquots. With moist samples or solutions enough concentrated hydrochloric acid was used to produce a concentration of 18 per cent acid in the mixture. After the hydrolysis was completed, the solution was concentrated under reduced pressure to dryness, and adjusted to a volume such that one ml. contained approximately two μg . of inositol.

Assay Procedure: Five-ml. portions of the basal medium were placed in 50-ml. Erlenmeyer flasks. Aliquots of the sample prepared as above are added to various flasks in order to cover the range of one to 0.1 μg . of inositol per ml., in the final solution. At the same time a series of flasks was prepared which contained 10 to 0.05 μg . of inositol per ml. Enough water was added to each flask to produce a final volume of 11 ml. The flasks were sterilized in an autoclave (15 pounds for 15 minutes), inoculated, and placed in a water bath at 30°C. for 16 hours. The contents of each flask were then examined quantitatively for turbidity in a photoelectric colorimeter. A standard curve was drawn relating colorimeter readings (turbidity) to micrograms of inositol.

It was found essential to maintain constant temperatures in all flasks. Variations of 1°C. vitiated the results. For this reason, a water bath was used in preference to the usual type of incubator in which variations in temperature frequently are observed in different parts of the cabinet.

Woolley¹⁷² reported on the biological specificity of inositol for rats and yeast. Of the compounds tested only meso-inositol, mytilitol, soy bean cephalin, and inositol hexacetate were active in the rat; of these, only meso-inositol was 100 per cent active for the yeast. Mytilitol had about 10 per cent activity for yeast, which Woolley believed might have been due to contamination with inositol. Inositol monophosphate and tetraphosphate had about five per cent and two per cent of the activity of meso-inositol. Inosose, an oxidation product of inositol, was inactive, thus making it appear doubtful that this compound acts as an intermediate in the metabolism of the vitamin.

The yeast-growth method of Alkin, Schultz, Williams, and Frey,¹⁰⁴ given in the pyridoxin discussion, is easily adopted to the assay for inositol. It has certain advantages over the methods described above.

PYRIDOXIN

Following the isolation of thiamine (vitamin B₁) from the vitamin B complex, it was soon apparent that the "vitamin B₂," under which designation all remaining B vitamins other than thiamine were grouped, was

172. Woolley. 1941. J. Biol. Chem. 140, 461-466.

of a multiple nature. Goldberger and Lillie¹⁷³ and Chick and Roscoe¹⁷⁴ reported a dermatitis produced in rats fed a diet deficient in this "vitamin B₂" complex, having "pellagra-like" characteristics. György and co-workers separated this complex into two fractions, one the real vitamin B₂ (riboflavin) and the second containing the factor preventing rat pellagra which he named vitamin B₆. This was subsequently differentiated from the human pellagra factor (now recognized as nicotinic acid) and likewise the dog anti-blacktongue factor which Elvehjem, Madden, Strong, and Woolley¹⁷⁵ recognized as nicotinic acid. The "rat pellagra" was termed acrodynia. In 1938 the isolation of crystalline vitamin B₆ was announced independently by five groups of workers—Lepkovsky,¹⁷⁶ Keresztesy and Stevens,¹⁷⁷ György,¹⁷⁸ Kuhn and Wendt,¹⁷⁹ and Ichiba and Michi.¹⁸⁰ Keresztesy and Stevens¹⁷⁷ reported their crystalline compound had a formula C₈H₁₁NO₃. Stiller, Keresztesy, and Stevens¹⁸¹ the following year reported vitamin B₆ to be 2-methyl-3-hydroxy-4,5-(hydroxymethyl)pyridine, further proof of which was supplied by Harris, Stiller, and Folkers.¹⁸² The synthesis of the vitamin was accomplished by Harris and Folkers¹⁸³ and simultaneously by Kuhn, Westphal, Wendt, and Westphal.¹⁸⁴

The function of this vitamin is unknown beyond the fact that it prevents or cures acrodynia in rats. Deficiencies may be manifest by convulsions in pigs, dogs, rats, and chicks. Certain types of anemia have been attributed to deficiencies of the vitamin. Waisman³¹ characterized pyridoxin as follows:

Pyridoxine (vitamin B₆, rat-antidermatitis vitamin, C₈H₁₁NO₃·HCl, a hydroxymethyl pyridine derivative).

Properties: Water-soluble. Less soluble in ether, alcohol, chloroform, and fat. Destroyed on exposure to light.

Function: Not definitely established. May be involved in fatty acid metabolism or synthesis of fat from protein.

Symptoms Associated With Deficiency: Indefinite. May be involved in certain muscular derangements. Possible role in prevention of certain anemias.

Requirement: Animal experiments indicate requirement is approximately that of thiamine.

Occurrence in Natural Foodstuffs: Chiefly whole wheat, soy bean, milk, beef liver, yellow corn, beef kidney, brewers' yeast, pork muscle, cabbage.

Pyridoxin stimulates yeast growth. It is required in nutrition of *Streptococcus hemolyticus* and certain other hemolytic streptococci as well

as lactic acid bacteria, such as *Streptobacterium plantarum*. Möller, Zima, Jung, and Moll¹⁸⁵ have shown that 2,4-dimethyl-3-hydroxy-5-hydroxymethyl pyridine had slight pyridoxin activity and that 2,4,5-trimethyl-3-hydroxy pyridine had no activity when determined with a strain of *Streptobacterium plantarum*. Bohonos, Hutchings, and Peterson¹⁸⁶ reported the vitamin to be required by *Lactobacillus casei* ϵ , *Lactobacillus arabinosus* 17-5, and a strain of *Lactobacillus delbruckii* but not by the strains tested of *Lactobacillus pentosus*, *Lactobacillus lactis*, and *Leuconostoc mesenteroides*. Those strains not requiring external sources of the vitamin were found capable of synthesis. *Lactobacillus casei* ϵ was able to store an amount of the vitamin above its physiological requirements when grown in a pyridoxine-containing medium. Consequently its reaction to increasing increments of pyridoxin added to an otherwise pyridoxin-free medium were quantitatively variable. The amount of pyridoxin necessary for maximum growth and acid production depended upon the size of inoculum. Also pyridoxin requirements increased as the oxygen tension of the medium was reduced. No derivatives of pyridoxin were as active as the vitamin, though the diacetyl derivative had about 80 per cent of the activity of the vitamin whereas the triacetyl derivative was inactive. In the rat these compounds were equally potent and of the same activity as the vitamin.¹⁸⁷ Substitution of bromine for the hydroxyl of the hydroxymethyl group resulted in still lower activity. Other derivatives had about 30 per cent of the activity of the vitamin.

Landy and Dicken⁶⁸ employed *Lactobacillus casei* ϵ in an assay for pyridoxin, described later in this chapter. The objections offered by Bohonos *et al.* probably will be encountered in this procedure.

Using a colorimetric method for determination of pyridoxin, Scudi,¹⁸⁸ following studies of urinary elimination, has shown that a small amount of the vitamin is altered at the 4-hydroxymethyl group. A larger fraction is conjugated, presumably through the 3-hydroxyl group by man and the dog but not by the rat. Scudi¹⁸⁸ has shown that water-soluble extracts of rice bran also contain free and conjugated forms of pyridoxin. Whether these combined forms are similar to those found by Snell, Guirard, and Williams,¹⁸⁹ discussed below, is not known.

Williams, Eakin, and McMahan's¹⁶⁸ Method for Assaying for Pyridoxin. One of the first microbiological methods for the assay of this vitamin was that of Williams, Eakin, and McMahan¹⁶⁸ based on the growth response of the Gebrüder Mayer strain of *Saccharomyces cerevisiae*. The method is similar to the yeast-growth method of Williams *et al.* for the assay of thiamine.

The basal medium contains the following components:

Sucrose.....	20.0 gm.
Potassium dihydrogen phosphate.....	2.0 gm.
Ammonium sulfate.....	3.0 gm.
l-Asparagine.....	3.0 gm.
Calcium chloride.....	0.25 gm.
Magnesium sulfate.....	0.25 gm.
Boric acid, zinc sulfate, thallium chloride, manganese chloride.....	1.0 mg. each
Ferric chloride.....	0.5 mg.
Copper sulfate.....	0.1 mg.
Potassium iodide.....	0.1 mg.
Vitamin-free hydrolyzed casein.....	0.2 gm.
Biotin.....	0.2 µg.
Calcium pantothenate.....	300.0 µg.
Folic acid.....	0.5 µg.
Inositol.....	5.0 mg.
Thiamine hydrochloride.....	20.0 µg.
Distilled water to make 1 liter	

Assays are carried out in bacteriological test tubes. These are conveniently supported by a wire or metal rack which may be steamed. The standard pyridoxin solution and solutions for analysis are added to the tubes. Standard tubes in triplicate contain 0, 0.05, and 0.1 ml. of a standard solution containing 0.004 µg. of pyridoxin per ml., or 0, 0.0002, and 0.0004 µg., respectively. Various amounts of tissue extracts from 0.01 to 0.1 ml. are pipetted with a syringe-type micropipette.

Enough basal medium is placed in a separate flask to supply two ml. per tube for all tubes under test and to this are added two ml. of pyridoxin-free liver extract and two ml. of pyridoxin-free yeast extract per 100 ml. of basal medium. Another 10 to 15 ml. of medium is put into a small flask to be used in seeding. The medium, racks of tubes, a 10-ml. graduated pipette, and a one-ml. graduated pipette are steamed in the autoclave at 100°C.(212°F.) for 10 minutes and then cooled to room temperature. The small flask of medium is seeded from an agar slant. The yeast is suspended uniformly and the number of milligrams of moist yeast cells per milliliter of solution is determined by the use of a photoelectric colorimeter and the appropriate calibration curve. By calculation, enough of this suspension is taken to seed the larger flask with 0.05 mg. of moist yeast suspension per 100 ml. of solution. After introduction of the yeast suspension and thorough shaking, two ml. of the medium are added to each tube in the test. The tubes are placed in a 30°C. water bath for a growth period of 15 hours.

The turbidity produced in the various tubes after 15 hours' incubation is quantitatively determined in a photoelectric colorimeter. When the tubes are removed from the incubator, they are placed in the refrigerator for 10 minutes to arrest the rate of growth of the test organism. They are then removed and diluted with five ml. of saturated chlorothymol solution. If the test consists of only a few tubes, only the dilution with chlorothymol is necessary. Before reading in the turbidimeter, the tubes are shaken vigorously, then allowed to stand for a few moments to allow the air bubbles to rise and break, suspended again by less vigorous shaking, and read.

Pyridoxin-Free Liver Extract: Five grams of liver paste (Wilson Laboratories 1-20) are mixed with 195 ml. of water and autoclaved 15 minutes at 15 pounds pressure, cooled to room temperature, and adjusted to pH 1 with HCl. Ten grams of Fuller's earth are added and the mixture is shaken intermittently several times a day for four days. The supernatant liquid is then decanted, adjusted to pH 4.5 to 5 and pipetted into test tubes (five-ml. portions) which are plugged and autoclaved at 15 pounds for 15 minutes. Three days later the tubes are again autoclaved as before.

Pyridoxin-Free Yeast Extract: Five grams of Difco Bacto yeast extract are treated in the same manner as the liver paste.

A standard curve (response to pure pyridoxin) is obtained with each set of assays. The samples for assay are dosed at increasing levels of concentration and the pyridoxin content of each tube is read from the standard curve. Usually three or more concordant results at different dosage levels are averaged to obtain a final figure. A random selection of assay values obtained from single cultures showed a percentage deviation from the mean of 4.7 per cent.

Few data are available regarding the pyridoxin content of tissues and no direct comparison of this method with others was made. It appears, however, that values obtained by this method are considerably lower than the "vitamin B₆" values obtained by animal and chemical assays. Since the method as outlined seems to give consistent assays and recoveries for free pyridoxin, the authors were of the opinion that there may be other chemical substances present in tissue extracts which function as "vitamin B₆" in animal tests. Rat assays by the method of Conger and Elvehjem¹⁹⁰ give considerably higher values.

Siegel, Melnick, and Oser^{190a} encountered difficulty in completely removing pyridoxine from the yeast and liver preparations. The use of Lloyd's reagent was more effective. "To the acidified (pH 1.0) liver and yeast extract solutions, described by the original authors,¹⁶⁸ are added 2 gm. of Lloyd's reagent and the suspension is shaken occasionally during the next 24 hours. After filtration the solution is treated again with the same quantity of the adsorbent. The mixture is then centrifuged, and the clear supernatant removed, adjusted to pH 4.5 to 5.0, bottled, and sterilized in the autoclave for 15 minutes at 15 pounds pressure." Other growth factors were also removed, necessitating their replacement. Biotin content of the medium was increased to 0.1 μ g. and the casein hydrolysate to 2.5 ml. per 100 ml. of basal medium. Tryptophane was added in concentrations of 0.2 mg. per 100 ml. of medium.

The method of Williams *et al.* did not allow for complete extraction of bound pyridoxine. Siegel *et al.* recommended autoclaving test suspensions of solutions for 30 minutes at 15 pounds pressure in 2 N sulfuric acid to render bound forms of the vitamin available for the yeast. The results agree with those obtained by chemical and biological assays.

Atkin, Schultz, Williams, and Frey's Method for Pyridoxin Assay. Since the discovery of the growth-promoting effects of pyridoxin for yeasts,¹⁹¹ yeast-assay methods for this vitamin have been investigated. The method devised by Atkin, Schultz, Williams, and Frey¹⁹² is claimed to have distinct advantages over the previously proposed methods in that the technic has been simplified and the medium improved, principally because of the choice of yeast for its specific response to pyridoxin. The technic of the assay is fully described by Atkin, Schultz, and Frey.¹⁹³

The assays are carried out in matched pyrex test tubes, 18 x 150 mm., with lips. Culture tubes without lips were not found suitable. Test tubes having an outside diameter of 17.8 to 18 mm. inclusive, when measured at the point of path of the light beam of the photoelectric colorimeter, were considered adequate. The tubes were matched, after cleaning, by filling with distilled water, and transmission tests made in a suitable

photoelectric colorimeter, such as the Lumetron 400.¹⁹⁴ Tubes showing less than one per cent deviation from the reference tube are satisfactory.

Previous to running an assay a calibration curve, showing the relationship between yeast concentration and per cent absorption, is prepared, using commercial compressed yeast. In all measurements the test tubes contain 10 ml. of suspension. This curve is convenient when standardizing the concentration of the inoculum used in the assay.

Because the method used in the determination of pyridoxin may also be employed for the determination of other vitamins, such as pantothenic acid, biotin, and inositol, it is convenient to prepare individual solutions of the various components of the basal medium and to combine them in the different ways required by the several methods. The basal pyridoxin-free medium contains the following ingredients for each five ml.: sugar and salts solution, 2.5 ml.; potassium citrate buffer, 0.5 ml.; casein hydrolysate, 0.5 ml.; thiamine solution, 0.25 ml.; inositol solution, 0.25 ml.; biotin solution, 0.10 ml.; calcium pantothenate, 0.125 ml. For a set of 40 tubes, for example, forty times the above amounts are measured into a mixing cylinder and diluted to 200-ml. volume.

The ingredients of the basal medium are prepared as follows:

Sugar and Salts Solution: One liter contains 200 grams of C. P. glucose (anhydrous), 2.2 grams of monopotassium phosphate, 1.7 grams of potassium chloride, 0.5 gram of calcium chloride ($\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$), 0.5 gram of magnesium sulfate, 0.01 gram of ferric chloride, and 0.01 gram of magnesium sulfate.

Potassium Citrate Buffer: One liter contains 100 grams of potassium citrate ($\text{K}_2\text{C}_6\text{H}_5\text{O}_7 \cdot \text{H}_2\text{O}$) and 20 grams of citric acid ($14\text{H}_2\text{C}_6\text{H}_5\text{O}_7 \cdot \text{H}_2\text{O}$).

Casein Hydrolyzate Solution: Eighty ml. of S.M.A. Corporation "vitamin free" casein hydrolyzate (10 per cent solution) neutralized to pH 4 to 6 (alkacid paper) and diluted to 100-ml. volume.

Thiamine Solution: Ten micrograms per ml.

Inositol Solution: One mg. per ml.

Biotin Solution: S.M.A. Corporation¹⁹⁵ biotin concentrate diluted so that it contains approximately 0.8 μg . per ml.

Calcium Pantothenate Solution: Two hundred μg . per ml.

A strain of *Saccharomyces carlsbergensis*, No. 4228, is carried on Difco malt slants. A slant is incubated for 24 hours at 30°C. and is then stored in the refrigerator for not more than two weeks. To prepare an inoculum for the assay, a fresh slant is prepared 24 hours earlier and incubated at 30°C. A quantity of fresh growth is removed by a sterile wire loop and suspended in 10 ml. of sterile 0.9-per cent saline solution in a colorimeter tube. The concentration of the yeast is estimated with the photoelectric colorimeter and is adjusted to a concentration of one mg. of moist yeast per ml. with addition of sterile saline.

For the assay, five ml. of the basal pyridoxin-free medium are placed in each test tube, plus a solution of the unknown extract or of pure pyridoxin hydrochloride together with water to make a total volume in each tube of nine ml. The tubes are plugged and steamed 10 minutes, cooled, and inoculated with one ml. each of the yeast suspension. The tubes are then shaken at 30°C. for 16 to 18 hours and the yeast growth is estimated in the photoelectric colorimeter. A reference curve which consists of a series of tubes containing 0, 5, 10, 15, 20, 30, and 40 millimicrograms of pyridoxin, is included in each assay run.

It is desirable to make turbidity readings at both 16 and 18 hours and to average all results to obtain the estimated value. All values are reported on the basis of pyridoxin hydrochloride employed as a reference standard.

It has been found that more reproducible results are obtained if the tubes are shaken throughout the growth period. A shaking machine, such as those devised for the Kahn test, and fitted with a suitable test tube holder, is placed in a water or air thermostat maintained at 30°C.

Although pyridoxin is relatively soluble, it is extracted from most plant and animal tissues with difficulty. Williams *et al.*¹⁹⁶ found that autolysis increases the pyridoxin contents of animal-tissue extracts. Atkin *et al.* have not found this method applicable to foods and tissues. The efficiency of extraction was found to depend upon the volume of extraction medium as well as the presence of acid. For most substances extraction with 180 ml. of 0.055 N sulfuric acid yielded maximal values. Insoluble materials should be powdered, if dry, or macerated with water in a Waring Blendor or its equivalent. A portion containing between two and four micrograms of pyridoxin is suspended in 180 ml. of 0.055 N sulfuric acid (one ml. of 10 N sulfuric acid and 179 ml. of water). The suspension or solution is heated in an autoclave at 20 pounds pressure for one hour, then cooled, neutralized to pH 5.2, and diluted to 200 milliliters. If the solution is turbid it is centrifuged and the clear supernatant liquid is used for the assay. In exceptional cases, such as white flour, the turbidity remains but can be removed if the extract is treated with a knife point of clarase at 37°C. for 30 minutes, followed by centrifugation. Wheat and wheat products require more acid to give maximal pyridoxin values; 180 ml. of .44 N sulfuric acid (eight ml. of 10 N sulfuric acid and 172 ml. of water) yielded nearly maximal values.

Enzymic hydrolysis may be used also, though digestion with clarase did not always yield values as high as those from acid hydrolysis. Some soluble vitamin concentrates were found to contain a bound form of pyridoxin which was not active in the test until acid autoclaved or enzymically digested. The enzymic digestion is conducted as follows:

A portion of the sample containing between two and four μ g. of pyridoxin is suspended in a small quantity of water in a graduated test tube, 0.5 ml. of potassium citrate buffer (pH 5.2) is added, and the volume is made to 10 ml. The tube is steamed for 30 minutes, cooled, and a quantity of clarase equal to the weight of the sample, but not less than 100 mg., is added. A few drops of benzene are added, and the tube is tightly corked and incubated for three days at 37°C. or two days at 45°C. At the end of the incubation the tube is steamed for 20 minutes and the contents are diluted to 200 ml.

Another strain of yeast is apparently satisfactory for assaying pyridoxin. Burkholder¹⁹⁶ used *Saccharomyces oviformis*, No. 782 (Northern Regional Research Laboratory, U.S.D.A.) and the basal medium proposed by Williams for his strain of *Saccharomyces cerevisiae*.

In a detailed study of the nutrition of *Streptococcus lactis* R Snell, Guirard, and Williams¹⁹⁷ observed that natural products contained a substance which could be derived from pyridoxin by metabolic processes, which far surpassed pyridoxin in its physiological activity for this organism. This substance was tentatively called "pseudopyridoxin." Later Snell¹⁹⁸ showed that if heat sterilization was avoided, pyridoxin had little growth-promoting activity for this organism. Activity was restored on autoclaving with the basal culture medium; the degree of activity increasing with the period of heating. The effect was traced to interaction

196. Burkholder. 1943. Amer. J. Bot. 30, 206-211.

197. Snell, Guirard, and Williams. 1942. J. Biol. Chem. 143, 519-530.

198. Snell. 1942. Soc. Expt. Biol. and Med. Proc. 51, 356.

during autoclaving, between pyridoxin and the amino acids of the medium; presumably “pseudopyridoxin” or a substance of similar high activity for the organism was formed in small amounts. Snell and Guirard¹⁹⁹ noted that alanine in large amounts could completely replace pyridoxin as a growth factor for *Streptococcus lactis* R, while glycine inhibited growth. Glycine inhibition could be reversed by addition of pyridoxin or dl-alanine. β -alanine, dl-serine, and dl-threonine also showed inhibitory activity but to a lesser degree. Alanine, glycine, serine, and threonine are among the amino acids essential for this organism. Pyridoxin is also required by *Lactobacillus casei* ϵ but alanine is incapable of replacing the vitamin for this organism. The fact that alanine is capable of replacing pyridoxin in the nutrition of *Streptococcus lactis* R suggests that the vitamin may be synthesized by the organism from alanine.

Snell, Guirard, and Williams’¹⁰⁷ Method for Assay of “Pseudopyridoxin.” For the assay of the pyridoxin-like substance which has great activity for *Streptococcus lactis* R a sample microbiological method was used, though at the present writing the significance of this material is not known. The assay procedure does not give true values for this substance, but rather, it is determined in terms of pyridoxin.

For assay purposes the following medium was used:

	Amounts per 250 ml. basal medium
Solution 1.....	250 ml.
Hydrolyzed casein.....	5.0 gm.
Sodium acetate.....	6.0 gm.
Tryptophane.....	0.05 gm.
Cystine hydrochloride.....	0.1 gm.
Water to make.....	500.0 ml.
Solution 2.....	5 ml.
Adenine sulfate.....	100.0 mg.
Guanine hydrochloride.....	100.0 mg.
Uracil.....	100.0 mg.
Water to make.....	100.0 ml.
Glucose.....	5.0 gm.
Solution 3.....	1.0 ml.
Thiamine hydrochloride.....	1.0 mg.
Calcium pantothenate.....	1.0 mg.
Riboflavin.....	1.0 mg.
Nicotinic acid.....	1.0 mg.
Folic acid concentrate*.....	0.001 mg.
Biotin.....	0.004 mg.
Water to make.....	20.0 ml.
Inorganic salts**	
Solution A.....	2.5 ml.
Solution B.....	2.5 ml.

* Folic acid concentrates are prepared according to the method of Mitchell, Snell, and Williams, 1941, J. Am. Chem. Soc. 63, 2284.
** These are the same salt solutions employed in the Lactobacillus assay methods, i.e., Snell and Strong, 1939, Ind. Eng. Chem., Anal. Ed. 11, 346.

The assay organism is *Streptococcus lactis* R (American Type Culture Collection No. 8043).

Acid-hydrolyzed casein is prepared by refluxing 50 grams of Labco vitamin-free casein with 500 ml. of constantly boiling hydrochloric acid for eight to 10 hours. Excess hydrochloric acid is removed by repeated concentrations *in vacuo*. The resulting sirup is dissolved in water, adjusted to pH 3, and shaken for 10 minutes with one part of activated charcoal (Darco G-60) to 10 parts of solids and then filtered.

Assays are carried out in test tubes. For the standard curve, tubes containing from 0 to three μ g. of pyridoxin are prepared. Various amounts of tissue extract are selected by experiments which are approximately equivalent in growth effect to these amounts of pyridoxin. All tubes are diluted to five ml. with water and five ml. of the basal medium is added. Tubes are plugged with cotton and then sterilized at 15 pounds pressure for 10 minutes. After cooling to room temperature, they are ready for inoculation. Cells for inoculum are prepared by transferring from a stab culture of the test organism to a tube containing 10 ml. of basal medium supplemented with three μ g. of pyridoxin. This culture is incubated at 30°C. for 16 to 30 hours before use. The cells are centrifuged out aseptically, then resuspended in 10 ml. of 0.9-per cent saline solution, and an aliquot of this suspension is diluted to barely visible turbidity. One drop of the diluted suspension is used to inoculate each assay tube. The tubes are then incubated at 30°C. for a growth period of 16 hours. Turbidities of the resulting cultures are determined with a photoelectric colorimeter. Results are expressed in terms of pyridoxin, i.e., the number of micrograms of pyridoxin which produces the same growth effect as the sample in question. The actual amount of the growth-promoting material present is unknown.

In rat tissues, Snell, Guirard, and Williams noted that the amount of pseudopyridoxin paralleled that of the pyridoxin in the ration and not the pseudopyridoxin content. Rats maintained on low-pyridoxin diets excreted very little pyridoxin or pseudopyridoxin, while those maintained on high-pyridoxin diets excreted large amounts of both substances. Animal passage apparently converts part of the ingested pyridoxin to the more highly active (for *Streptococcus lactis* R) pseudopyridoxin.

Streptococcus lactis R does not utilize the pyridoxin molecule as such but converts traces of it to the more highly active "pseudopyridoxin" which is utilized. No detectable decrease in the amount of pyridoxin in a medium following maximum growth of the organism was noted. According to this view the pseudopyridoxin rather than the pyridoxin molecule is necessary for utilization. More information on this interesting observation is needed before one may fully understand the role of this factor.

By X-ray treatment Beadle and Tatum²⁰⁰ secured mutants of *Neurospora* species which had lost their ability to synthesize certain of the B vitamins. An assay method for pyridoxin has been reported by Thompson, Isbell, and Mitchell,²⁰¹ employing a mutant of *Neurospora crassa*. Stokes, Foster, and Woodward,²⁰² employing a mutant of *Neurospora sitophila* which Beadle and Tatum had reported to be unable to synthesize pyridoxin, found that this mutant could produce the vitamin under certain conditions, namely, in pyridoxin-free media supplied with ammonium-nitrogen and maintained at a pH between 6 and 7. The parent strain was able to synthesize the vitamin at all pH levels up to 7.8 (at which no growth occurred) and from varied nitrogen sources.

200. Beadle and Tatum. 1941. Natl. Acad. Sci. Proc. 27, 499-506.

201. Thompson *et al.* 1943. J. Biol. Chem. 148, 281-287.

202. Stokes *et al.* 1943. Arch. Biochem. 2, 235-245.

Stokes, Larsen, Woodward, and Foster's *Neurospora* Assay for Pyridoxin. Even though cultural conditions of the organism influence its requirements for pyridoxin, Stokes *et al.*^{202a} reported successful microbiological assay for pyridoxin employing a "pyridoxinless" mutant of *Neurospora sitophila*. The assay is based on dry weight of mold mycelium produced, and consequently is not influenced by highly colored or turbid solutions. The organism is apparently not influenced by "pseudopyridoxin." The results agree closely with those of animal assays on the same or similar biological materials.

Stock cultures of the organism are carried on Sabouraud's agar slants (maltose, 38 gm.; Bacto-peptone, 8 gm.; Bacto-malt extract, 2 gm.; agar, 20 gm.; 1 liter of water). Pink or orange colored spores usually are abundant at the upper portion of slant in four to five days. After sporulation, the cultures are stored in the refrigerator until used. Fresh cultures are prepared every three weeks.

Basal Medium. The basal medium, in twice the desired final concentration is as follows:

Sucrose.....	30.0 gm.
Ammonium tartrate.....	10.0 gm.
Monopotassium phosphate.....	5.0 gm.
Magnesium phosphate.....	1.0 gm.
Sodium chloride.....	0.2 gm.
Calcium chloride.....	0.2 gm.
Ferrie chloride.....	10.0 mg.
Zinc sulfate.....	2.0 mg.
Biotin.....	8.0 μ g.
Distilled water.....	1.0 liter

The medium may be opalescent but this does not interfere with the assay. The zinc represses sporulation, which facilitates harvesting of the mold. The potassium dihydrogen phosphate buffers the medium initially at approximately pH 5, which is essential since growth without pyridoxin will occur if the pH rises above 5.8 to 6.0. Ammonium tartrate also aids in keeping the pH below the critical values, for as the ammonium ion is utilized by the organism, tartaric acid accumulates in the medium.

Assay Procedure. Five ml. aliquots of the basal medium are placed in 50 ml. Erlenmeyer flasks. A set of reference flasks is prepared containing 0.1 to 1.0 μ g. of pyridoxin (free base, not the hydrochloride). Blanks containing no pyridoxin are included. For unknown solutions, aliquots of 0.5 to 2.0 ml. are added to the basal medium. The flasks are plugged and sterilized at 15 pounds pressure for 15 minutes. After cooling, the flasks are inoculated with a spore suspension of *Neurospora sitophila*. The inoculum is prepared by removing with a platinum loop a small portion of growth, consisting primarily of spores, from an agar slant and making a uniform suspension in 10 ml. of sterile water. Each flask receives one drop of this suspension. Small variations in the number of spores inoculated do not affect the assay, though a very light inoculum may prevent the standard curve from rising to its normal maximum growth level of 40 to 45 mg. of mycelium. This may occur also if the culture is too old. A heavy inoculum may increase the growth in the blanks above the customary 1 mg. of mycelium.

The inoculated flasks are incubated at 30° for five days, during which time a pellicle or mycelium mat develops on the surface of the medium. After incubation, the cultures are steamed at 100°C. for five minutes and the mycelium harvested with a stiff wire needle. The mycelium mat is pressed dry between two paper towels, rolled into a small pellet, and dried at 100°C. for two hours. Glazed porcelain spot plates are convenient for handling the mycelium during drying and weighing. The dry mycelium is weighed to the nearest mg. on an analytical balance.

Preparation of Samples. Insoluble materials are ground or homogenized prior to extraction. An appropriate sample, generally 1 to 5 grams, is mixed with 40 ml. of 1 N HCl in a 250 ml. Erlenmeyer flask and autoclaved at 15 pounds pressure for one hour. If the sample is completely in solution, it is cooled and diluted to 50 ml.. If an

appreciable amount of insoluble material remains, the sample is filtered through paper, the filtrate washed twice with water, and the filtrate diluted to 50 ml.

Destruction of Thiamine. Thiamine in the sample must be destroyed since it stimulates growth of the test organism in the presence of suboptimum amounts of pyridoxin. A modification of the sulfite cleavage method of Schultz, Atkin, and Frey is used. Ten ml. of the extract are pipetted into a 50 ml. Erlenmeyer flask and 0.7 ml. of 10 N NaOH added, followed by 5 ml. of a freshly prepared one per cent solution of anhydrous sodium sulfite. The pH of the mixture is adjusted to 8 with 1 N NaOH, cresol red being used as an outside indicator. The cleavage of thiamine is carried out at pH 8 instead of pH 5 as recommended, because it was found that considerable destruction of pyridoxin occurs when solution of pyridoxin plus thiamine are treated with sulfite at pH levels of less than 8. Also the amount of sulfite is one-half that suggested by Schultz, Atkin, and Frey¹⁹¹ to avoid toxic effects encountered with larger amounts. However, it is sufficient to destroy 100 μ g. of thiamine. After adjustment to pH 8, the mixture is steamed at 100°C. for 30 minutes, cooled, and treated with an exact quantity of fresh two per cent hydrogen peroxide solution to destroy the excess sulfite. Usually five to 10 drops are required to reach the end point (p. 1030). The volume is made to 20 ml. with water and the sample is assayed for pyridoxin as described above.

It has been noted that with certain samples, such as peptone or malt extract, there is a tendency at higher aliquot levels for the pH of the medium to rise above the critical pH of 5.8. When this occurs, maximum growth of the organism is produced irrespective of the amount of pyridoxin present. This can be controlled by doubling the potassium dihydrogen phosphate concentration.

Though thiamine can partially replace pyridoxin in the nutrition of *Neurospora sitophila*, other growth factors such as nicotinic acid, pantothenic acid, p-aminobenzoic acid, riboflavin, inositol, folic acid, uracil, adenine, guanine, and xanthine do not stimulate the organism in presence of sub-optimum levels of pyridoxin.

FOLIC ACID

One of the as yet unidentified members of the B-complex has been named "folic acid" by Mitchell, Snell, and Williams²⁰³ because of its abundant occurrence among leaves and greases. Hutchings, Bohonos, and Peterson²⁰⁴ objected to this name because it does not suggest the material, yeast, from which it was first obtained nor its many abundant sources, such as liver, kidneys, milk, peptone, mushrooms, etc. They recommend to defer naming until its chemical identity is established.

This substance is probably identical with the "norite eluate factor" of Snell and Peterson¹⁴⁷ which serves as a growth factor for *Lactobacillus casei* ϵ . It was originally discovered in yeast extract by Snell and Peterson which was separated into two fractions. One is adsorbed on Norite A charcoal, the "norite eluate factor," and the second is the filtrate fraction which can be replaced by biotin. From the properties of a concentrate prepared from a water-soluble liver fraction, Snell and Peterson reported the eluate factor to be predominately a basic substance, though having some acidic properties. Some precipitation tests indicated the factor might be a purine or closely related compound. More information has been supplied by Hutchings, Bohonos, and Peterson,²⁰⁴ including a method of preparation. Heating a concentrate at 125°C. (257°F.) for 15 minutes with 1 N sulfuric acid resulted in 75-per cent loss in potency while 25-per cent potency was lost when heated with 1 N sodium hydroxide. Since the mate-

203. Mitchell, Snell, and Williams. 1941. Amer. Chem. Soc. J., 63, 2284.

204. Hutchings, Bohonos, and Peterson. 1941. J. Biol. Chem. 141, 521-528.

rial is acidic, it was suggested that inactivation by acid might be due to lactone formation, though unsuccessful regeneration experiments with alkali seemed to exclude this possibility. The factor is completely precipitated by mercury, zinc, and copper and to a lesser extent by silver, cadmium, barium, calcium, and nickel. Zinc offers some selectivity useful in further purification. It has fewer basic properties than previously thought. It is strongly adsorbed under acid conditions and is quantitatively adsorbed on norite, Fuller's earth, superfiltrol, and, to a lesser degree, on aluminum hydroxide $C\gamma$, aluminum oxide, and anthranilic acid, though elution from these latter substances is incomplete. It is insoluble in common organic solvents, with the exception of glacial acetic acid, formamide, and dioxane (only slightly soluble). The factor is not destroyed by pepsin, trypsin, ficin, yeast peptidase, or commercial phosphatase preparations. It is present in Labco vitamin-free casein and is not destroyed until the casein is completely hydrolyzed. Hutchings *et al.* suggest the factor is an integral part of the protein and does not become subject to attack until the protein is destroyed. The activity was destroyed by esterification with ethyl alcohol-hydrochloric acid at room temperature, and 50 per cent of the activity was regenerated by sodium carbonate hydrolysis. At least part of its acidity is attributed to a carboxyl group. Activity is destroyed by nitrous acid indicating the presence of a free amino group. In the presence of pyridine, the activity is destroyed by acetic anhydride or benzoyl chloride, also suggestive of an amino group.

Stokstad prepared a substance from solubilized liver believed to have properties of nucleotide in that it contained nitrogen and phosphorus and gave a positive Bial test for pentose. However Mitchell, Snell, and Williams²⁰³ reported their material to be free of phosphorus and to be 100 times more active than Stokstad's factor, suggesting that the latter's factor contained impurity. The nucleotide theory is also refuted by Hutchings *et al.* on the basis that organic phosphorus is not necessary for activity; and destruction and phosphorus liberation were not parallel. Mueller and Miller²⁰⁶ reported the "norite eluate factor" of Snell and Peterson was required by *Clostridium tetani* and that Stokstad's "nucleotide" was equally effective. Attempts to replace this latter factor with thymine and guanine were generally unsuccessful though indications from occasional experiments pointed toward a partial effect by thymine. Stokstad²⁰⁵ later agreed that his preparation was free of phosphorus. He reported preparations made from liver and yeast. The compound from liver gave a methyl ester which could be precipitated repeatedly from ethyl alcohol in a yellow gelatinous form without change in biological activity. Bladed crystals of the ester were obtained by slow evaporation of methyl alcohol solutions. From yeast a crystalline compound was obtained. The free acid of this had the same absorption spectrum in 0.1 N NaOH, pH 7, as the material isolated from liver. The methyl esters prepared from liver and yeast were hydrolyzed to yield preparations having

206. Mueller and Miller. 1941. *J. Biol. Chem.* 140, 933-934.

205. Stokstad. 1941. *J. Biol. Chem.* 139, 475-476; 149, 573-574, 1943.

equal potency for *Lactobacillus casei* ϵ . When assayed by the method of Mitchell and Snell²¹⁵ the preparation from yeast was only half as active as that from liver. This suggests the substances isolated from liver and yeast are different. Stokstad suggested the compound prepared from liver was identical with that obtained by Piffner *et al.*²¹¹ Half-maximum growth of *Lactobacillus casei* ϵ was obtained by both investigators with 0.00005 μ g. per ml. of their respective preparations. Elementary analyses agreed well with data presented by Piffner *et al.*

That this substance may be of importance in several fields of biology has been indicated. Hutchings *et al.* have found that growth of *Lactobacillus helveticus*, *Lactobacillus delbruckii*, *Propionibacterium pentosaceum*, and *Streptococcus lactis* were stimulated by addition of this factor. Growth of *Bacillus lactis acidi*, *Lactobacillus arabinosus*, *Lactobacillus pentosus*, *Bacillus brasicae*, *Leuconostoc mesenteroides*, and *Lactobacillus gayonii* were not stimulated, but in every case these organisms had synthesized significant amounts of the factor. In rats, Mitchell, Snell, and Williams²⁰³ reported slight growth increases, though Hutchings *et al.*²⁰⁷ have been unable to secure significant increases, which was suggested to be due to bacterial synthesis, as also suggested by Mitchell *et al.* Some evidence is at hand that this factor is required by the chick.²⁰⁷

Under certain dietary conditions, Hogan and Parrott²⁰⁸ have shown that chicks failed to grow and developed severe anemia curable by liver extracts. The existence of a specific factor was recognized and called "vitamin B_c" for which Hogan and O'Dell²⁰⁹ developed a chick assay. Mills, Briggs, Elvehjem, and Hart²¹⁰ reported a concentrate representing Peterson's "eluate factor" to prevent anemia in chicks. Piffner, Brinkley, Bloom, Brown, Bird, Emmett, Hogan, and O'Dell²¹¹ isolated Hogan's "vitamin B_c" as orange-colored spherulites which exhibited typical crossed extinction when crystallized from water. After repeated recrystallizations it separates into clusters of thin, yellow, sphere-shaped platelets. It did not melt at 360°C. (680°F.), but darkened and charred from about 250°C. (482°F.). An ash-free sample showed the following analysis: carbon 50.50, hydrogen 4.78, and nitrogen 19.91. The crystalline methyl ester shows no melting point, has only five per cent of the activity of the original acid, and can be converted to the acid. The acid form is highly active for *Lactobacillus casei* ϵ , half-maximum growth being produced by .00005 μ g. per ml. of culture medium. Piffner and his colleagues suggested that the "eluate factor," "folic acid," and Hogan's "vitamin B_c" are identical and proposed retention of the latter name until its chemical identity is established. Nielsen and Elvehjem²¹² and Martin²¹³ have demonstrated that folic acid is capable of counteracting growth inhibition of rats owing to succinyl-sulfathiazole and sulfaguanidine, indicating synthesis of the vitamin by

intestinal bacteria. Synthesis by the intestinal flora has also been suggested by Mitchell and Isbell.²¹⁴ The preparation of vitamin B₆ from beef liver has been described by O'Dell and Hogan.^{214a}

Mitchell and Snell's²¹⁵ Assay Method for Folic Acid. For the assay of folic acid, Mitchell and Snell have employed *Streptococcus lactis* R as the test organism. More recently, Landy and Dicken⁶⁸ have employed *Lactobacillus casei* ϵ in the assay. This procedure will be discussed in a subsequent part of this chapter, since by their medium other members of the vitamin B complex may also be assayed. The medium of Mitchell and Snell contains the following components:

Vitamin-free hydrolyzed casein.....	10 gm.
(Charcoal treated, Darco G-60)	
Sodium acetate.....	12 gm.
Glucose.....	20 gm.
Tryptophane.....	100 mg.
Adenine sulfate.....	20 mg.
Cystine hydrochloride.....	200 mg.
Guanine hydrochloride.....	20 mg.
Xanthine.....	20 mg.
Uracil.....	20 mg.
Thiamine chloride.....	200 μ g.
Pyridoxine hydrochloride.....	200 μ g.
Calcium pantothenate.....	200 μ g.
Riboflavin.....	400 μ g.
Nicotinic acid.....	200 μ g.
Biotin.....	0.4 μ g.
Inorganic salts, Solutions A and B.....	5 ml. each
Distilled water to 1 liter	
pH adjusted to 6.6 to 6.8	

This medium is a modification of that used by Snell and Peterson²¹⁶ for *Lactobacillus casei* ϵ in obtaining the "norite eluate factor." Adenine, guanine, uracil, and xanthine have been added since these compounds stimulate the growth of the test organism.²¹⁷

For preparation of the inoculum the above medium is diluted with an equal portion of distilled water and one mg. of liver extract (Wilson and Company, fraction B) is added per 10 ml. of medium. About 10 ml. of medium are used in each tube. *Streptococcus lactis* R is transferred from stock culture to the above medium, incubated for 14 to 30 hours at 30°C., centrifuged, and resuspended in sterile saline solution.

Assays are carried out in bacteriological test tubes. Each tube contains five ml. of the basal medium to which is added the prepared assay material. The final contents of each tube is then diluted to 10 ml. The tubes are plugged with cotton and sterilized at 15 pounds pressure for 15 minutes.

Standard tubes containing 0, 20, 40, 60, 100, and 200 mg. of liver extract B (potency = 1) are satisfactory for establishing the standard curve. Results are expressed empirically, assuming pure folic acid to have a potency of 40,000. Thus the potency is based upon the liver extract fraction B (Wilson and Company) which is assumed to have a potency of one.

It has been pointed out that too much charcoal treatment of acid-hydrolyzed casein results in a medium that supports growth of the test organism poorly, even in the presence of "folic acid." Perhaps this is the result of removal of p-aminobenzoic acid, since Isbell²¹⁸ has reported similar experience, alleviated by addition of the vitamin, in preparing the basal medium of Snell and Wright for nicotinic acid assay.

Growth responses by the test organism are measured turbidimetrically, using a photoelectric colorimeter.

NIACIN (NICOTINIC ACID)

Nicotinic acid is a vitamin. Its functions were given by Waisman³¹ as follows:

Nicotinic Acid (niacin, P-P vitamin, anti-blacktongue factor. $C_6H_5NO_2$, 3 pyridine carboxylic acid).

Properties: Most stable of water-soluble vitamins. Not affected by acids, alkali, heat.

Function: Component of two important coenzymes, coenzyme I (cozymase) and coenzyme II, both concerned in glycolysis and tissue respiration.

Symptoms Associated With Deficiency: Erythematous skin lesions. Inflammation of all mucous membranes. Anorexia. Loss in weight. Nervous disturbances. Dementia. Diarrhea. Frank pellagra with accompanying glossitis, dermatitis, etc.

Daily Requirement: Man, 15 to 23 mg. Woman, 12 to 18 mg. Children (1-12 years), 4 to 12 mg.; (12-20 years), 14 to 20 mg.

Occurrence in Natural Foodstuffs: Chiefly beef liver, peanut butter, beef kidney, chicken, pork loin, salmon, yeast (dry), ham, brown rice, whole wheat.

The vitamin activity of this compound in curing disease was first reported by Elvehjem, Madden, Strong, and Woolley.²¹⁹ It was reported later as a curative agent for deficiency diseases in other animals. Its function in nutrition of certain microorganisms has also been established. Knight²²⁰ showed that it stimulated development of *Staphylococcus aureus*; Koser, Dorfman, and Saunders,²²¹ the dysentery bacilli; Mueller,²²² *Corynebacterium diphtheriae*; Hornibrook,²²³ *Hemophilus pertussis*; and Rane and Subbarow,²²⁴ the pneumococcus.

Numerous methods have been proposed for assaying for nicotinic acid and its compounds. Many of them are not sufficiently specific. Frazer, Topping, and Sebrell²²⁵ assayed urine for nicotinic acid using *Shigella paradysenteriae*, Sonne, as the test organism. Later, Isbell, Wooley, Butler, and Sebrell²²⁶ reported quantitative assay for nicotinamide and related substances in blood, urine, and spinal fluid. Querido, Lwoff, and Lotosto²²⁷ used *Proteus* sp. for determining nicotinamide and related compounds in the same materials. Dorfman, Harwitt, Koser, and Saunders²²⁸ assayed milk, blood, urine, and saliva.

According to results of investigations of Lwoff and Lwoff²²⁹ the V-factor in blood which satisfies growth requirements of *Hemophilus influenzae* and *Hemophilus parainfluenzae* may be replaced by coenzyme I or II, which have been shown to be diphosphopyridine and triphosphopyridine

nucleotide, respectively, by Warburg. It cannot be replaced by adenylic acid, nicotinic acid, nicotinamide, diethylamide, o-dihydropropylnicotinamide, or the product formed when either coenzyme is kept at 100°C. and pH 8.5 for 20 minutes. Assays based on response of this organism when aliquots of blood, urine, and tissue were added to a basal medium free of the V-factor were made by Kohn,²³⁰ Pittman and Frazer,²³¹ and Kohn, Klein, and Dann.²³²

Since the V-factor is known to be comprised of coenzymes I and II and perhaps other related compounds, the assays for the V-factor are calculated with reference to the response of the test organism to coenzyme I. Schlenck and Gingrich²³³ have recently shown that nicotinamide nucleoside, a compound of coenzyme, can also function as the V-factor.

Hoagland and Ward's²³⁵ Method for Microbiological Assay for the V-Factor. In the methods mentioned above in which *Hemophilus* sp. have been used as test organisms, growth responses have been determined turbidimetrically, using photoelectric colorimeters. Since this technic may be completely unreliable in those instances in which insoluble or pigmented material containing V-factor are added to the basal medium, Hoagland, Ward, Gilder, and Shank²³⁴ observed that nitrate reduction can be used as a quantitative expression of its metabolic activity and that nitrite production in a standard medium may be used as a reliable measure of the V-factor content of materials. The complete assay procedure has been given by Hoagland and Ward.²³⁵ Sensitivity of nitrite determination permits use of such small aliquots of test material that color and turbidity do not interfere. The method of Shinn²³⁶ has been used for determining nitrites.

Preparation of Medium: The medium which has been found most satisfactory for quantitative determination of the V-factor is composed of two per cent of Difco proteose-peptone, .6 per cent of sodium chloride, and 0.2 per cent of sodium or potassium nitrate as the source of nitrite. After sterilization in the autoclave at 116°C. (240.8°F.) for 20 minutes, rabbit, sheep, or human blood was added.

Preparation of Inoculum: Standard inocula were prepared in five ml. of a stock broth composed of two per cent proteose-peptone, 0.6 per cent sodium chloride, 0.1 mg. of autoclaved hemin, and 0.06 µg. of purified coenzyme as the V-factor. Nitrate was omitted in order to prevent transfer of nitrite with the inoculum. Organisms carried on heated blood agar by weekly transfers were inoculated into a tube of stock broth and incubated overnight at 37°C. After three transfers in stock broth the organisms were ready to use. When 0.1 ml. of such a culture was inoculated into 10 ml. of medium no multiplication or reduction of nitrate occurred unless the medium contained V-factor.

A number of strains of *Hemophilus influenzae* have been used in the development of this technic. Although strains were found to differ markedly in the rate and total amount of nitrite produced in a given medium, when the same strain was used for the production of a standard curve and the determination of the V-factor content of a given test material, results were obtained which checked closely with determinations of the V-factor with other strains.

To run after p. 922

lary white diarrhea. In 200 bacteriological examinations, Rettger was unable to detect bacteria, molds, or other microorganisms except *Salmonella pullorum*. The blood was ruled out as a source of infection and examinations of the oviducts showed them as a rule to be sterile except at or near the cloaca. The views of Horowitz³⁸ substantiated those of Rettger. It was believed that autosterilization of the oviduct is due to the following: (1) phagocytosis, (2) mechanical action of the walls of the oviduct, and (3) bactericidal action of the secretions. Success in preserving eggs with sodium silicate was cited as an indication that sound fresh eggs are as a rule sterile. The fact that many market eggs are decomposed was accounted for by storage under unfavorable circumstances, i.e., filthy conditions and warm temperature and the fact that bacteria are given an opportunity to enter when the gelatinous coating is removed from eggs during washing and handling.

Decomposition of eggs, according to Haines and Moran,⁶⁴ was occasioned mainly by bacteria which entered the egg after laying. They showed that the shell is porous and permits bacteria to enter. Relative temperatures of the egg and its environment were found to be important. If the temperature of the egg was higher than a fluid containing bacteria in which it was immersed, bacteria were readily drawn into the egg by suction as the egg cooled. About the same conclusions were reached by Rievel⁶⁵ from results secured with a different technic.

Bacteria in Egg White. Available data on this subject are conflicting. Many of those who have found no bacteria in egg white have assumed that this component of the egg possessed a bactericidal action. Wurtz,⁶⁶ Rettger Sperry,⁶⁷ Scholl,⁶⁸ Horowitz,³⁸ Turro,⁶⁹ Laschtschenko,⁷⁰ and Riezicka⁷¹ reached the same conclusions. Sperry⁷² showed that cold-storage eggs exhibited the same action. Bainbridge,⁷³ Poppe,³⁷ Hoppert,⁵⁹ Mauer,³² and Laschtschenko⁷⁰ found no germicidal action. Mauer was especially interested in *Escherichia coli*. Rettger and Sperry employed *Clostridium putrificum* and *Bacillus edematis maligni* as the test organisms. Egg white in test tubes was heavily inoculated with the test organisms and incubated under conditions favorable to their development. In the yolk, which was treated in the same manner, evident putrefaction set in, while in egg white, bacteria were destroyed since examination with the microscope failed to demonstrate presence of cells. Haines⁵³ observed that 98 per cent of whites of eggs which he examined were sterile.

. Hadley and Caldwell,⁴¹ in their extensive investigation of eggs, reported data which confirm that of Rettger and Sperry. Fleming and

Allison ⁷⁴ have shown that egg white contains a bacteriolytic, bactericidal, and bacterio-inhibitory substance which they named *lysozyme*. On a susceptible bacterium, the lytic power was still manifest when the egg white was diluted 50,000,000 times. The bacteriolytic power of egg white from different species of birds varied considerably when tested on the same organism. The egg yolk had a very slight antibacterial action on a susceptible organism, but when tested on a less susceptible organism, it apparently had no antibacterial power and to some extent inhibited the bactericidal action of the egg white. Egg white inhibited the growth of most of the pathogenic bacteria tested, and had a definite lethal or lytic effect on many of these bacteria, e.g., *Staphylococcus*, *Streptococcus*, *Menigococcus*, *Eberthella typhosa*, *Bacillus anthracis*, etc. The lysozyme of egg white resisted peptic and tryptic digestion, and following the ingestion of raw egg white by mouth the number of streptococci in the feces was temporarily much reduced. Egg white added to blood *in vitro* maintained its antibacterial action, and when injected intravenously into an animal it conferred on the blood serum of the animal marked antibacterial powers which were evident after several hours.

May's ⁷⁵ work on the germicidal action of egg white on *Salmonella pullorum* may be mentioned here. He went over some earlier work in which dilutions of egg white one to 20 were used and which seemed to indicate an indifferent action of the egg white towards the bacteria used with the exception of *Bacillus proteus zenkeri* which was killed off quickly in high dilutions. In the repeated experiments, eggs from one to five days old were used. They had been kept in an ice chest until used. In general, May was unable to demonstrate definite germicidal or inhibitory effect in one to 20 or higher dilution of egg albumen. He did observe, however, inhibition by undiluted egg white or by very low dilution.

Sharp and Whitaker ⁷⁶ found that the germicidal power of egg white was markedly influenced by hydrogen-ion concentration, which decreases rapidly during the first few days' storage of untreated eggs in a ventilated room. These investigators explained the conflicting results of previous workers on the basis that they did not take into account the age of the eggs and, consequently the hydrogen-ion concentration, when testing the germicidal action of the white. For vegetative cells of *Bacillus subtilis* egg white was very germicidal at all hydrogen-ion concentrations, while the spores were more resistant. The toxic substance which killed the vegetative cells was separated from the egg white by dialysis, the diffusate becoming nongermicidal on standing. The hydrogen-ion concentration corresponding to that at the time the egg was laid, permitted growth, while the hydrogen-ion concentration corresponding to that of whites which have been stored a few days in air, was germicidal to a number of common organisms. In another paper, Sharp ⁷⁷ placed hydrogen-ion concentration first among the factors involved in the preservation of eggs.

Bacteria in the Egg Yolk. Practically all investigators are agreed that yolk contains the greater number of bacteria. Hadley and Caldwell ⁴¹ found 8.7 per cent of 2,520 eggs infected in the yolks. Mauer ³² is said to have found 18.1 per cent of the yolks to be infected. Bushnell and Mauer ⁴⁰ found 23.7 per cent. Rettger's data were corrected to show a yolk infection of 9.9 per cent, covering examinations over a period of three years. Qualitative studies of the bacteria in eggs have been reported by several investigators. Rettger ³⁹ gave the following bacteria:

Fresh eggs	Number of times found
Staphylococcus, usually <i>aureus</i> or <i>albus</i>	74
Subtilis, usually <i>B. mesentericus</i> or <i>B. ramosus</i>	60
<i>Escherichia coli</i> and closely related organisms.....	43
Proteus group.....	30
Streptococcus.....	14
Micrococcus (tetragenus, etc.).....	9
Streptothrix.....	6
Diphtheroid bacillus.....	5
Putrefactive anaerobes.....	5
<i>Pseudomonas fluorescens</i>	2
Mold.....	4
<i>Bacillus mucosus</i>	3
Mixed.....	2

Hadley and Caldwell studied 40 different strains isolated from eggs. Among them were found 11 cocci, 28 rods, and one spirillum. No streptococci were reported. They observed no member of the hemorrhagic, septicemia, intestinal, proteus, colon, enteritidis, typhoid dysentery or diphtheria groups. *Salmonella pullorum* was not observed in 2,520 eggs. No anaerobic bacteria were sought. Hadley and Caldwell noticed more different types of bacteria on control plates than on egg plates. The percentage of infected eggs found by different investigators is given below:

Name	Examined	Per cent infected
Rettger.....	3,510	9.5
Rettger (10 ml. samples).....	647	3.86
Bushnell and Mauer.....	2,759	23.70
Hadley and Caldwell.....	2,520	8.70
Mauer.....	600	18.10

Hadley and Caldwell's work may be summarized as follows:

Of 2,510 fresh eggs from 65 hens examined by the indirect method, 8.8 per cent showed infection of the yolk. None of 111 whites examined showed the presence of bacteria while the yolks of the same eggs gave a percentage of 4.5 per cent, less than the average of 8.8 for the series. The percentages of infection obtained for individual hens per year varied between 2.8 and 15. No hen laid sterile eggs during the whole year. No correlation was observed between the percentage of infection for any individual hen and the degree of fecundity. Approximately the same amount of infection was found among fertile eggs (6.9 per cent of 422

eggs examined) as among infertile eggs (8.9 per cent infected out of 315 eggs). Infection of eggs seemed to have no relation to hatchability. No definite seasonal variation of infection was observed, nor did the eggs from pullets and hens vary greatly as to bacterial content.

Wagner⁷⁸ described *Bacillus mycoides* var. *ovoathylicus* as capable of producing alcoholic fermentation in eggs without evidence of putrefaction. Infected eggs cannot be distinguished from sound eggs by superficial examination. Wagner stated that the membranes remained intact and the only visible evidence of infection was a number of lens-shaped colonies about one millimeter in diameter distributed through the outer yolk. A great number of eggs were examined by Wagener,⁷⁹ especially for *Pseudomonas aeruginosa*. This organism was found in only a few specimens.

Liquid Egg. Few food products are more perishable than eggs when they have been removed from their shells. Spoilage is greatly inhibited, however, by using high-quality eggs and breaking them under strictly sanitary conditions. In view of the fact that spoilage is due largely to activities of microorganisms, studies of the microbial population become important. Eggs have been found to contain pathogenic bacteria, which suggests a possible health hazard, though slight, of liquid eggs. This product cannot be pasteurized as can other products to make them safe. Mallmann and Churchill⁸⁰ have stressed the significance of low numbers of bacteria. The keeping quality of egg contents was said to be determined by the number of putrefactive bacteria which are in the product when prepared. This number, in turn, is influenced by methods used in processing.

Liquid eggs are liable to be heavily seeded with bacteria. Their chemical constitution makes them quite susceptible to microbial attack if they are not handled under the most satisfactory condition. This has been shown by Thomas⁸¹ and by the Bristol Health Committee.⁸² The former found extensive bacterial contamination in imported frozen eggs, while the latter authority found coliform bacteria to be frequently present in liquid eggs imported into England from China. Other microorganisms, such as aerobic sporeformers, Staphylococci, and a few Streptococci, were also found. Since liquid-egg products are usually used for making pastries, they were examined also for these bacteria. Coliform bacteria seemed to be destroyed by baking but the other species appeared able to survive. This was not considered to be a menace to health but was believed to interfere with the keeping quality of the products.

Mallmann and Churchill's⁸⁰ Procedure for Detecting Bacteria in Liquid-Egg Meats During Processing. This is a direct microscope method which the authors believed could easily be applied to plant control. Samples may be collected and taken to the laboratory or films may be made in the field and mailed to the laboratory. The procedure, as given by Mallmann and Churchill, follows:

78. Wagner. 1916. Ztschr. f. Untersuch. der Nahr. u. Genussmtl. 31, 233-237.

79. Wagener. 1929. Rev. in Bull. Inst. Pasteur 27, 938.

80. Mallmann and Churchill. 1942. Ice and Refrig., May 1942.

81. Thomas. 1935. Pub. Health 48, 320-322.

82. Brit. Med. J., 1936, p. 365.

Collection of the Sample. For plant control, samples of the product can be collected at any point after the egg meats have been churned to give an even distribution of the bacteria in the entire mass.

Samples may also be taken as scrapings from equipment to detect sources of contamination or samples may be taken of individual eggs if desired.

The sample is collected by dipping the tip of a sterile wooden applicator into the egg meats to be examined.

Preparation of the Film Slide. A drop of the egg meat is discharged on a clean microscope slide placed beneath a standard-thickness oiled paper cut so that an area one centimeter wide the length of the slide is exposed. The egg meat is deposited at the end of the slide. Using another clean slide the egg meat is spread evenly over the exposed area by drawing the end of the second slide over the egg meat and drawing the excess ahead of the slide and leaving behind a continuous film of constant thickness. The spreader slide should be held lightly in the fingers at an angle of 45° to the slide to be smeared. The waxed paper margins on the slide serve to hold the egg meat within a straight channel and act as a guide to give a constant depth to the film. A clean spreader slide must be used for each sample.

After the egg meats have been spread the slide is removed and the waxed paper guide is discarded. The smeared slide is dried in a horizontal position. A warm table may be used to facilitate drying.

Staining the Film. After the film is thoroughly dried it is immersed in the following staining bath:

- 1 gm. methylene blue (certified for bact. use)
- 500 ml. 95 per cent ethyl alcohol
- 5 ml. conc. hydrochloric acid.

The slide should remain in the staining bath from three to five minutes.

The slide is removed from the staining bath and dipped into tap water. The slide should remain in the water just long enough to remove the excess stain from the film without decolorizing the bacteria. Care should be taken not to leave the slide too long in the water, because the film will take up water and wash off the slide.

The film should be dried in a horizontal position using a warm table if examination is to be made immediately.

Examination of the Stained Film. The film is examined by means of the microscope using a 1.8 to 2 mm. oil immersion objective and 10X eyepiece. Artificial light passed through a red Wratten filter No. 24 or its equivalent should be used. White or blue lights fail to give sufficient contrast to show the faintly stained blue organisms. The bacteria appear bluish-black in color with a red background due to the filter. Only the bacteria retain the stain. A very slight amount of color is retained in the background of egg meats to aid in focusing the microscope.

The area of the microscope field should be determined and the reported count should be the number of bacteria per square centimeter of film. One hundred microscopic fields should be counted to obtain an accurate count.

If the diameter of the microscope field is .17 mm. with a 10X eyepiece, there will be 4,424 fields per square centimeter of film area.

It will be observed that in this procedure no attempt has been made to report the results of the direct microscope method by the customary bacteria per gram. The number of organisms per gram is not important provided the evaluating system gives the number of bacteria on a comparable basis so that the number in one sample can be compared with another. This is accomplished in this test by maintaining a film of constant thickness so that the number of bacteria per square centimeter of film represents a constant volume. Standards for this procedure can be set by an analysis of a large number of counts based on eggs from various sources with diverse bacteria contents.

A comparison with the plate count can be made roughly, but it must be remembered that the microscope procedure shows all the stainable bacteria, and that not all these bacteria will necessarily grow on nutrient agar medium used at present for measuring the bacteria counts of egg meats. In one sample of egg meats examined the bacteria

count by the plating method at 20°C. (68°F.) for 72 hours was relatively low, whereas the direct microscope count was high. When the agar plates were incubated for seven days many colonies appeared that were invisible in 72 hours. At this time the direct microscope count and the plate counts were comparable.

An approximation of the relative relationship of the direct microscope count and the plate count follows:

RELATIONSHIP OF DIRECT MICROSCOPE COUNT AND PLATE COUNT

Direct microscope count number per 1 sq. cm. film	Plate count bacteria per gm. egg meat
4,500	750,000
450	75,000
45	7,500

The writers stated that these figures were approximations and were based on too few samples to be dependable comparisons even if comparisons were permissible.

Frozen Eggs. This has become a large industry in America. Numerous reports have been made concerning the microorganisms involved. The marked susceptibility of eggs to bacterial decomposition, as well as the fact that unfit eggs may be used, presents some interesting bacteriological problems. Stiles and Bates⁷ prepared frozen eggs in the laboratory from second-grade eggs. Such a product generally had a bacterial content of 1,000,000 per gram. Frozen eggs prepared from spots, rots, and blood rings gave a bacterial content of 4,000,000 to 1,000,000,000 per gram with a relatively high content of *Escherichia coli* and streptococcus. Pennington *et al.*⁸³ pointed out the difficulties of proper sanitary control of the industry. Keith⁸⁴ suggested that the addition of sucrose to the broken eggs before freezing would improve their quality. In France, where during hot weather many cases of food poisoning have been traced to cakes and pastries with so-called cream fillings, bacteriological examinations of canned frozen eggs revealed a mixed flora of molds and bacteria. French food-control officials advised careful control of the industry. Bordas⁸⁵ believed that frozen eggs could be a menace to health unless they were of good quality before freezing and kept frozen until consumed.

Mauer,³² Pennington,⁸⁶ and Stiles and Bates¹⁷ pointed out the evil consequences that might result from the use of unsound eggs. Mauer believed that when a bad egg was encountered, the hands and utensils with which it came in contact should be washed in clean water or treated with live steam. Similar observations were made by Pennington and Robertson.⁸¹ Stiles and Bates reported that frozen-egg products prepared in the laboratory in Washington from second-grade eggs comprising "undersized," "dirties," and "weak eggs" generally showed a total bacterial content of less than 1,000,000 organisms per gram, while dried eggs prepared from the same grades usually contained a total bacterial content of less than 4,000,000 organisms per gram, both kinds containing but a very small number of *Escherichia coli*; from a bacteriological standpoint they were

considered to be an edible product. Frozen products made from "light spots," "heavy spots," "blood rings," and "rots" showed bacterial counts generally ranging from about 1,000,000 to 1,000,000,000, while dried eggs made from the same grade contained from 4,000,000 to more than 1,000,000,000 organisms per gram with a relatively high proportion of *Escherichia coli* and Streptococci in both the frozen and dried material, indicating an unwholesome article, unfit for food, and only useful for technical purposes. While the principle of preserving food by the abstraction of moisture and refrigeration was recognized as a perfectly legitimate business when applied to wholesome products, no amount of freezing and desiccation will rejuvenate eggs already decomposed in whole or in part. The experiments reported on frozen- and dried-egg products kept at low temperatures indicated during the early part of storage a general rise in the bacterial content with a subsequent decline in numbers. This decline was more marked in the case of dried eggs containing 10 per cent added sugar than in similar products to which no sugar was added, indicating that the sugar had acted as an antiseptic, as might be expected; such an addition might, therefore, be employed to conceal inferiority. The egg industry in this country constitutes so valuable a source of food that it is essential that undesirable practices attending any branch of it be remedied. Increased care in the production and handling of this highly perishable article on the part of the producer and the buyer will, to a large extent, bring about desired conditions.

Samples of imported Chinese frozen eggs, analyzed by Verge and Grasset,⁸⁷ gave counts on gelatin of 85,000 per gram of yolks, 5,000 for the whites and 30,000 for the whole eggs. After standing for 48 hours at laboratory temperature, these counts had increased to 3,600,000, 360,000, and 4,000,000, respectively. On account of the large number of bacteria in frozen eggs, Cartier⁸⁸ believed that this method of preservation should be used only when other methods could not be employed. He reported counts as high as 104 million per gram in mixed whites and yolks.

Quick-freezing according to Swenson and James⁸⁹ yielded a better product than slow-freezing. They also observed some improvement in quality from carbonation just before freezing. Combination of use of one per cent of salt and quick-freezing was also a good practice. Nielsen and Garnatz⁹⁰ later stated that from 10 to 14 per cent of salt added to egg products retarded bacterial growth during mixing and freezing and, combined with the action of $-18^{\circ}\text{C}.$ ($-4^{\circ}\text{F}.$) storage temperature, reduced the number of viable bacteria to less than 10 per cent of the original count in the first month of storage.

Frozen eggs, in some cases, may be shipped long distances. Those from China are best known. The Ministry of Health of Great Britain⁹¹ found frozen eggs packed in China suitable for consumption when properly

packed and handled. Bacterial counts were low and no communicable disease had been traced to such a product.

Schneider's⁹² Procedures for Microbiological Examination of Frozen Eggs. The bacteriological examination of egg products involves different factors for each different class, but only methods for the microbiological examination of frozen egg products are to be considered at this time.

The major portion of the output of the frozen egg industry is utilized in the preparation of food products that receive little or no heat processing during their manufacture. It is, therefore, essential that the frozen egg products used be free from large numbers and types of viable microorganisms, which may induce rapid spoilage or be of potential danger to health when incorporated in foods.

Microbiological methods for the examination of frozen egg products should include procedures for the determination of (1) the total numbers of microorganisms and (2) the incidence of types of microorganisms that may be dangerous to health or conducive to food spoilage.

While the presence of large numbers of viable microorganisms in frozen egg products is indicative of the use of poor quality shelf stock, unsatisfactory manufacturing procedures, or insanitary plant conditions, a high incidence of coliform organisms and hemolytic types of bacteria may be, in addition, indicative of potential danger to health.

The following microbiological methods are proposed:

I. SAMPLING

EQUIPMENT

(1) Electric drill with auger (12" x 1"), (2) alcohol burner, (3) alcohol (95% C₂H₅OH), (4) absorbent cotton, (5) two tablespoons, (6) sample containers (sterile 1 qt. or 1 pt. Mason jars), (7) hammer and steel strip (12" x 2" x 0.25") or other tool for opening cans, (8) water pail, (9) towels, and (10) record book, pencils, etc.

PROCEDURE

Select a representative number of cans from lot (square root of total). Note and record all marks of identification, for example: firm name and location, brand, type product, code or lot numbers, etc. Sterilize auger and tablespoons by sponging off with alcohol-soaked cotton and heating in flame of alcohol burner. Wash drill and spoons in pail of water and re-sterilize after each container sampled. Open the containers aseptically. Drill three cores equidistant between side and center of can and one-third of periphery apart. Transfer drillings from can to sample container with sterile tablespoon. Examine product organoleptically by smelling at opening of drill-hole after sample is removed. (Heat produced by electric drill intensifies odor of egg material, thus facilitating the organoleptic examination.) Record odors as normal, putrid, sour, or musty.

Refrigerate samples with dry ice if analysis is to be delayed or sampling point is at some distance from laboratory. Carry out sampling procedure under as nearly aseptic conditions as possible.

II. ANALYTICAL PROCEDURE

PREPARATION OF SAMPLE

Thaw frozen egg material as rapidly as possible in order to prevent an increase in the numbers of microorganisms present and at temperatures sufficiently low to prevent destruction of microorganisms (20°-30°C.). (Frequent shaking aids in thawing the frozen material. Thawing temperatures may be maintained by the use of a water bath.)

Thoroughly mix each thawed sample with spoon or electric stirrer before analysis. Prepare a 1-10 dilution by aseptically weighing 5.0 grams of egg material into a wide-mouthed glass-stoppered bottle containing 45 grams of sterile physiological salt

92. Schneider. 1939. Assoc. Off. Agr. Chem. J. 22, 625-628; also 25 (1941), 740-745.

solution (0.85% NaCl per 1,000 ml. distilled water) and 1 tablespoonful of glass shot. Agitate the 1-10 dilution thoroughly to insure complete solution or distribution of the egg material in the diluent. Prepare serial dilutions from 1-100 to 1-100,000,000 for inoculation into various culture media. Inoculate all media within 15 minutes after the sample is prepared.

PLATE COUNTS

Inoculate duplicate plates with 1 ml. portions of all dilutions from 1-1,000 to 1-1,000,000. (Nutrient agar or dextrose agar may be employed as plating media.) Incubate one set of plates at 20°-30°C. for 3 days and the second set of plates at 37°C. for 3 days. Express final results as numbers of viable microorganisms per gram of egg material. (Uniformly higher counts are always obtained on plates incubated at 20°-30°C.)

INCIDENCE OF COLIFORM GROUP

Inoculate 1.0 ml. portions from suitable dilutions (1-10 to 1-100,000,000) of egg material into fermentation tubes of lactose broth. Incubate at 37°C. for 24-48 hours.

Streak Levine's eosin methylene blue agar plates from all lactose broth cultures showing gas production. Incubate plates at 37°C. for 24-48 hours. Examine E.M.B. agar plates for colonies of microorganisms of the coliform group.

Inoculate from colonies of the coliform types of bacteria appearing on E.M.B. agar plates to nutrient agar slants. Incubate at 37°C. for 24 hours. Purify cultures for further study.

Obtain biochemical reactions of purified cultures by Kovac's test, indol production; methyl red (M.R.) and Voges Proskauer (V.P.) tests; and Koser's sodium citrate test, utilization of sodium citrate as the sole source of carbon.

NOTE: Follow procedure recommended in *Standard Methods of Water Analysis*, 8th Ed., 1936, of The American Public Health Association for Biochemical Reactions.

HEMOLYTIC TYPES OF MICROORGANISMS

Inoculate petri plates with 1 ml. portions of all dilutions from 1-100 to 1-1,000,000. Pour plates with veal-infusion agar containing 6% of defibrinated horse, sheep, or rabbit blood (0.6 ml. of blood per 10 ml. of media). Cool agar to 40°C. and add blood just prior to pouring plates. (Incubate plates for 24 hours at 37°C.) Express final results as numbers per gram.

ANAEROBIC TYPES OF MICROORGANISMS

Inoculate tubes containing chopped meat media with 1 ml. portions of all dilutions from 1-10 to 1-100,000. Incubate for 3 days at 37°C.

DIRECT MICROSCOPE COUNTS

Place 0.01 ml. of the 1-10 or 1-100 dilutions of egg material on a clean microscope slide and spread over an area of 1.0 sq. cm. Permit the smear preparation to dry on a level surface at 30°-40°C. Proceed as directed in *Standard Methods of Milk Analysis* of the American Public Health Association (latest edition). Multiply total count by 10 or 100, since the original smear preparation was made from a 1-10 at 1-100 dilution in order to obtain the numbers of bacteria per gram of egg material.

III. CULTURE MEDIA

STANDARD METHODS MEDIA

Prepare as recommended in *Standard Methods of Water Analysis*, 8th Ed., 1936, of The American Public Health Association.

Nutrient agar, lactose broth, Levine's eosin methylene blue agar, tryptophane broth, methyl red-Voges Proskauer peptone medium, and Koser's sodium citrate medium.

Other media include (a) *Dextrose agar*.—Standard nutrient agar plus 1.0% dextrose. (b) *Veal infusion agar*.—Ground lean veal, 500.0 grams, and distilled water, 1000.0 ml. Infuse overnight in refrigerator and strain through cheesecloth without

pressure. Make up to original volume and skim off any fat. Steam in Arnold 30 minutes and filter through paper. Add:

	<i>per cent</i>		<i>grams</i>
Peptone (Difco)	1.0	or	10.0
NaCl	0.5	or	5.0
Agar	1.5	or	15.0

Steam in Arnold to dissolve. Adjust reaction to pH 7.6 and steam in Arnold 15 minutes. Filter through Buchner funnel with paper pulp mat, by the aid of suction. Use egg albumen for clarification when necessary. Distribute 10 ml. quantities into test tubes or 80 ml. quantities into bottles. Sterilize at 15 lbs. pressure for 20 minutes. Final pH 7.4. (For hemolytic tests agar should be cooled to 40°C. and 6% of defibrinated horse, sheep, or rabbit blood added prior to pouring plates (0.6 ml. of blood per 10 ml. of media.)

(c) *Holman's cooked meat medium (alkaline)*.—Distilled water, 1000 ml., ground fresh lean beef, 500 grams, bacto-peptone, 5 grams, and C. P. NaCl, 5 grams. Infuse the beef-water mixture overnight in refrigerator. Strain through several layers of cheesecloth and press out broth, retaining the meat press cake. Add distilled water to the infusion to make 1 liter. Add the peptone and heat in the Arnold or boil 10 minutes. Filter, and add salt. Add normal NaOH until alkaline to phenolphthalein. Heat in Arnold 15 minutes to clear and filter. Distribute the pressed-out beef remaining from the infusion into medium sized tubes (150 x 20 mm.), approximately 2 grams into each tube, and add 10 ml. of the cleared alkaline broth. Sterilize in the autoclave at 15 lbs. pressure for 15 minutes. Final reaction should be pH 7.2-7.4. Store in refrigerator. Prior to using, boil the tubed medium for at least 10 minutes to expel adsorbed oxygen and cool promptly in a water bath.

The Manual Methods for Pure Culture Study of Bacteria of the Society of American Bacteriologists should be used as a guide for the further study of microorganisms obtained in the cultural procedures described.

In order to determine whether these procedures were satisfactory, Schneider⁹² submitted identical samples to several collaborators who used the recommended methods in examining them. Most of the plate counts reported by all collaborators were in agreement with respect to grading the samples as of good or bad bacteriological quality. Several exceptions were observed but were believed to be within the possibility of experimental error. Results reported for the incidence of coliform bacteria were in close agreement for all samples but three. Wider discrepancies were observed in the results of microscope counts made by two collaborators.

Organoleptic tests⁹³ have been applied to frozen eggs by federal food-control officials. These involve the organs of touch, taste, and smell. Results of this method are determined largely by the experience of those who make the tests and are not always confirmed. This was shown in an alleged adulteration of frozen eggs in 1941.

DRIED EGGS

Production of dried eggs has become a great industry during recent years. One reason for this is the amount required for export. Production capacity for 1941 was anticipated to exceed 150 million pounds.⁹⁴ The chemical nature of eggs makes it necessary to use every precaution possible

93. Notices of Judgment Under the Federal Food, Drug and Cosmetic Act, Federal Security Agency, March 1943, No. 3508.

94. Stateler, 1941. *Indus.* 13, 40 *et seq.*

in securing a high-grade raw product and to handle it carefully in clean apparatus during drying. While bacteria are generally credited with much of the deterioration in egg products, it is known that enzymes may be involved as well as metals. Traces of the latter may lead to rancidity. The microbial content of dried eggs has been found to be high. Haines⁹⁵ mentioned three reasons for this: the desire to store the highest grade eggs in the shell and the use of lower grade eggs for drying, introduction of many microorganisms on the shell into the egg during breaking, and multiplication of bacteria in the stored egg powder.

Some of the early work on dried eggs was carried out by Stiles and Bates⁷ with eggs which were dried under laboratory conditions and on samples which were imported. Bacteriological examination of 75 samples of dried imported egg whites showed that nine out of 75 samples, or 12 per cent, contained 1,000,000 organisms or less per gram while 46 samples, or 61.3 per cent, showed 10 million or more per gram. Fifty-two per cent of samples of commercially dried eggs showed 100 million or more bacteria per gram. Whether these heavy bacterial loads were due to low-grade eggs or to faulty handling during and after drying could not be stated. The bacterial numbers just quoted were apparently only those species which grew on aerobic plates. Pennington⁸³ reviewed the methods of manufacture of dried eggs and reported results of bacteriological examinations of many samples, histories of which were known. For breaking purposes reputable firms use all under-sized or over-sized, dirty, cracked, or shrunken eggs. Such eggs should be candled, broken, and dried under chilled conditions. The lowest count on flaky dried eggs was 65,000 per gram and the highest count was 20,000,000 per gram. The average count for 48 samples was 3,600,000. The number of *Escherichia coli* varied from 0 to 1,000,000. About three times as many bacteria were found in the dried product as in the liquid egg. Ross⁹⁶ examined 248 samples of dried eggs which had been stored at different temperatures, finding that the desiccated egg loses a large percentage of the bacteria originally present if stored for a relatively short period. A more rapid diminution of bacteria results if the storage takes place at higher temperatures. He stated that a product even from spots and worse, might satisfy the ordinary bacterial tests if stored for a period of a few months.

Sartory and Flament⁹⁷ examined some desiccated commercial egg powders and found a strict aerobic flora. *Staphylococcus citreus*, *Escherichia coli*, *Bacillus subtilis*, etc., were isolated. Ten thousand aerobic bacteria per gram in dried eggs were reported by Marcardier and Goiyon.⁹⁸ *Penicillium glaucum* was always present. Since dried eggs are not sterile, they are subject to bacterial decomposition. These authors stated that each package of egg powder should bear the date of manufacture and should not be shipped far. Wyant⁹⁹ reported the bacteriological examination of two

samples of dried eggs. One sample contained 40,000,000 per gram and the other 60,000,000. Two specimens of dried eggs analyzed at the Michigan Agricultural Experiment Station¹⁰⁰ contained 40,000,000 and 66,000,000 bacteria per gram. Lactose fermenting bacteria were absent. In a study of the bacteriology of dried eggs, DeBord¹⁰¹ found a variable content of bacteria. In general, there was agreement between the quality of the raw product and the method of dehydration. The counts in whole eggs dehydrated by the spray process varied from 350 in the good egg to 1,160,000 in the "spots." In the product prepared by the vacuum drum process from whole egg the counts varied from 45,000 in the good egg to 2,400,000 in the "rots." The yolk, in general, showed more bacteria than the white. The count in stored dehydrated egg depends on several factors, such as initial count, length of time in storage, and temperature in storage. An initial count of 350 in a good egg decreased to 300 in 10 months when held at 37°C.(98.6°F.) and at 20°C.(68°F.), while a count of rotten eggs decreased to 1,350 when held at 37°C. In another sample of rotten eggs the count increased from 235,000 to 430,000 in three months.

Bacteriological Examination of Dried Eggs. Stiles and Bates⁷ stated that solid egg products should be examined on the gram basis. Weigh five grams into a sterile glass-stoppered bottle and add enough water to make a one to 10 dilution. Addition of sterile glass beads to the bottle before agitation facilitates disintegration of the sample. After thorough shaking the sample should be plated in dilution of one to 10,000 and higher to about one to 10 million. Incubate the plates from three to five days at both 37°C.(98.6°F.) and room temperature.

Presence of coliform bacteria may be determined by inoculating fermentation tubes containing various media, such as brilliant green bile, formate ricinoleate broth, or other similar media. Presence of Streptococci may be determined by staining films prepared from the fermentation tubes.

Bacterial Standards for Dried Eggs. Questionable sanitary quality of eggs and conditions under which they were dried, prompted food control officials to seek methods which might be used in the industry. These have included examination of the eggs, inspection of establishments in which they are dried and finally examination of the final product. Among the latter are "plate counts" which have been used for examination of other foods. Plate count standards for dried eggs have been difficult to determine. Consequently there is no agreement with respect to what they should be. This prompts one to wonder why those which are used were adopted and on what grounds. Goresline^{101a} recently said that high bacterial counts indicate laxity of supervision and faulty equipment in the egg drying plant. He failed, however, to tell what a high count is in dried eggs.

Circular 583, Eggs and Egg Products of the U. S. Department of Agriculture, gives no bacterial standards. Von Loesecke in his *Drying and Dehydration of Foods* stated that dried whole eggs should not contain

100. Mich. State Bd. Agr., 59th Ann Rpt., 1920.

101. DeBord. 1925. J. Agr. Res. 31, 155

101a. Goresline. 1943. Proc. Inst. Food Tech., 70-76.

more than 300,000 viable organisms per gram. More detailed standards have been issued by the Quartermaster Corps of the U. S. Army, as follows:

“Standard Bacterial Plate Count—

“a. Shall not exceed one hundred fifty thousand (150,000) per gram. The plating medium shall be Standard Nutrient Agar and the plates shall be incubated at 37°C. for 48 hours.

“b. Coliform organisms shall not exceed one hundred (100) per gram when examined under methods prescribed in the Standard Methods for Examination of Dairy Products, American Public Health Association, 1941.

“c. Yeast and mold count shall not exceed one hundred (100) cells per gram respectively when incubated on Potato Dextrose Agar at 32°C., for 48 hours.”

Those who use plate counts frequently ascribe to them an accuracy which they do not possess. Plate counts are subject to many errors. They have been discussed in several other places in this book and for milk especially on page 320. The quotation from Wilson's, *The Bacteriological Grading of Milk* applies as much to dried eggs as it does to milk.

In the dairy industry the results secured from the agar plate are now said to be merely an “estimate.” This word has a general meaning, to calculate approximately, roughly appraise or to form an opinion without the use of precision apparatus or technic. Breed (1927) who suggested use of the term *estimate*, said that as far as milk was concerned, no one had ever actually counted the number of bacteria in a cubic centimeter of milk in the same way that the number of people in a room have been counted. If this is true for milk how much more it would hold for a product like dried eggs.

Another objection is that “plate counts” do not consider the type of organism which is involved. This is more important than numbers. A “count” of microorganisms in egg powder of 100 per gm. might be much more significant than a count of 200,000 per gm. The former might be harmful pathogenic bacteria while the latter might be harmless saprophytes no more significant in dried eggs than in any other food. “Plate counts” have been largely used as whips in the past over the heads of manufacturers and others who did not understand them and who were led to believe that they were significant. Bacteriologists should be the first to wake up to the false implications which are involved.

Fermentation of Egg Whites. Egg whites contain sugar which tends to cause darkening during storage. In order to prevent this trouble, egg whites are fermented to remove the sugar content. Resulting also from the fermentation is an increase in acidity and thinning of the thick portions which allows the mucin to be removed. According to Conquest¹⁰² the best temperature for this is 26.7 to 29.4°C. (80 to 85°F.) and the time two days. During fermentation, foam forms and the product is improved by removal of various types of foreign matter. Success of fermentation is measureable by the odor of the finished product. At one time, high acidities resulting from fermentation were neutralized but the practice has been discontinued. Conquest stated that the Chinese once used ammonium hydroxide, depending on subsequent treatment, to get rid of the excess.

102. Conquest. 1941. Food Indus. 13, 95.

Aerobacter aerogenes and *Escherichia freundii* were reported by Stuart and Goresline¹⁰³ to be the predominating bacteria in normal fermentations of egg white. In abnormal fermentations members of the genera *Proteus*, *Pseudomonas*, and *Serratia* predominated. In these fermentations proteolysis occurred and a longer time was required for the egg white to reach a pH of 6.1 which had been correlated with reduction in free sugar. Egg white from fresh eggs with a low initial number of bacteria fermented slowly and irregularly. When many bacteria were present, fermentation was rapid and regular. Egg white separated from storage eggs with a large number of bacteria, which originated in the egg and not from shell contamination, fermented slowly. No members of the genera *Aerobacter* and *Escherichia* were found in these whites. A much better product was secured when they were present than when the fermentation was carried on by other species.

PRESERVATION AND STORAGE OF EGGS

Eggs are produced mainly during a few months of the year. Consequently, it is necessary to resort to methods of preservation. The nature of the egg and its chemical constitution make it very susceptible to attack by microorganisms. Jones and DuBois¹⁰⁴ classified the various methods of preservation as follows: (1) low temperatures; (2) airtight packing; (3) sealing with various agents, and (4) immersing in preserving solutions. They believed that the bacteria which were contributed to the egg by careless methods of handling were more important than the congenital forms. Sharp¹⁰⁵ reviewed much literature on this subject. He believed that oil coating of the shell was the cheapest and most successful method of preserving eggs. This prevents loss of moisture and carbon dioxide. Swenson¹⁰⁶ also described a vacuum-oil process which delayed deteriorative changes in eggs.

Gas Storage of Eggs. Continued storage of eggs presents many problems which have to be considered. A balance must be maintained between factors each of which alone has distinct disadvantages. Moran¹⁰⁷ stated that the relative humidity should not exceed 85 per cent during storage at $-6^{\circ}\text{C}.$ ($31^{\circ}\text{F}.$) else mold development ultimately penetrates the shell. At this humidity, however, evaporation is appreciable (.12 per cent per week). This results in a larger air cell with loss of quality in the egg. In view of this fact, the ideal situation is to store eggs in a saturated atmosphere, or nearly so, and use some method of inhibiting molds. "Gas storage" in atmospheres of carbon dioxide which inhibits molds was believed to offer some hope. Some 60 per cent of carbon dioxide was required to completely inhibit mold development over nine months on eggs stored at $0^{\circ}\text{C}.$ ($32^{\circ}\text{F}.$). Lower amounts, such as $2\frac{1}{2}$ per cent, have but slight inhibitory value.

107. Moran. 1937. (Gt. Brit.) *Food Invest. Bd., Ann. Rpt. for 1936*, p. 53.

Ozone has been suggested as a preservative for eggs. The amount used in the atmosphere must be small and well controlled. Ten per cent of ozone in the air, according to Haines,¹⁰⁸ produced eggs which were "off" in flavor. Eggs treated with air with but three per cent of ozone did not have an unpleasant taste after 12 weeks' storage. Furthermore mold growth was inhibited on the eggs.

Candling of Eggs. The control of the commercial egg industry by chemical or bacterial analyses is very impracticable. Pennington⁶³ has pointed out that each egg is a package by itself and an analysis of it would in no way indicate the condition of the lot. This has made it necessary for those engaged in food control to look for other methods for determining the fitness of eggs for consumption. Candling has developed to satisfy this need. It consists in ascertaining the character of an egg by allowing light to penetrate the contents.¹⁰⁹ Different contrivances are used to do this. An electric light yields the most satisfactory results, since it is constant in intensity and quality. Many cheap types of candling devices are used. Benjamin¹⁰⁹ has described two common ones. The accurate use of the candling apparatus demands some experience before reliable results may be obtained. Pennington *et al.*¹⁰⁹ have published instructions for candling eggs. Those wishing a complete classified description of eggs before the candle and outside of the shell will be rewarded by reading this bulletin.

Jenkins and Hendrickson¹¹⁰ have reported an investigation on the accuracy of commercial grading of opened eggs. This was made by means of a bacteriological study of 2,052 individuals breaking stock eggs. These investigators found that despite careful candling a small number of these eggs (13.5 per cent) were found to contain more than 100 bacteria per ml. The remaining 86.5 per cent contained less than 100 per ml. They stated that "there was a progressive rise in the percentage of bacterial contamination through the following series: clean whole eggs, dirty whole eggs, clean cracked eggs, dirty cracked eggs, clean leaking eggs, and dirty leaking eggs." Eggs with weak yolks showed more bacteria than eggs with firm yolks. It was also determined, as by others, that some eggs contain bacteria which cannot be determined by appearance or odor. The composite samples of breaking stock eggs might contain from a few to many bacteria. Another candling device was described by Moran and Piqué.¹

Collection of Samples of Eggs for Bacteriological Examination. The difficulties of sampling food products for analysis are clearly brought out in analysis of eggs. Each egg is a separate package, the chemical and bacteriological condition of which does not necessarily indicate the situation for other eggs. About all the analyst can do is to select a sufficient number to allow him to generalize more readily than if but one egg were examined.

109. Those who are interested in candling eggs will find the following publications of special interest:

Benjamin. 1914. The interior quality of market eggs. N. Y. Agr. Expt. Sta. (Cornell Univ.) Bull. 353.

Pennington, Jenkins, and Betts. 1918. How to candle eggs. U. S. Dept. Agr. Bull. 565.

110. Jenkins and Hendrickson. 1918. U. S. Dept. Agr. Bull. 391.

The Food and Drug Manual, giving instructions to officials, analysts, and inspectors of the Bureau of Chemistry relating to procedure for the enforcement of the Food and Drugs Act of June 30, 1906, made the following statements concerning the collection of samples of egg products for bacteriological examination:

EGG PRODUCTS

Frozen Eggs. Before beginning operations, provide as many clean sterilized containers, preferably quart Mason jars, as there are samples to be drawn, also a two-inch ship auger, chisel, metal spoons, supply of alcohol, towels, and receptacles for hot water used in the frequent recleansing of the utensils. A few extra sterilized containers are desirable to provide for breakage or accident.

Before drawing the sample, all instruments used must be sterilized immediately before using. They must again be cleansed thoroughly and sterilized before being used on each subsequent subdivision of the sample collected. In drawing samples, cores sufficient to pack a quart jar should be taken midway between the center and circumference at equidistant points from each other. The cores can best be drawn by boring with a sterilized ship auger from the top to the bottom of the container after first removing, with a sterilized chisel, the surface layer of the frozen material. The cores from each container should constitute a separate subdivision of the sample.

The turnings or chips of the sample cores should be introduced into the sterilized container without permitting the material to come in contact with the fingers or any other contaminating object. When necessary, a sterilized spoon may be used to remove the material attached to the auger and pack it in jars. Such portions of the spoon as are touched by the fingers or any other contaminating object must not be permitted to touch the product. Nothing should be permitted to touch the inside of the container covers, which should never be inverted. The containers should not be opened, nor the interior exposed to the air longer than is absolutely necessary to admit the sample. After receiving its portion of the sample each container should be identified, sealed, and immediately placed on ice or in a sharp freezer.

The inspector should note carefully the condition of the product at the time of sampling, and record the appearance and odor. Samples which are satisfactory for bacteriological examination will also suffice for chemical analysis. In cases where deemed advisable, however, one or more original packages of the product may also be submitted.

All samples must be delivered to the laboratory in their original frozen condition. If delivery can be made in a short time, pack in sufficient ice to hold during transit. If the laboratory is at a distance, the subdivisions should remain in a sharp freezer until solidly frozen, after which they may be iced for shipment. It has been found that the samples may be shipped in good condition by wrapping the jars with waxed paper, then packing them tightly in a container with sawdust to prevent breakage. This container is then braced in the center of another container, such as a box or barrel, and is surrounded by sawdust over which sufficient water is poured while in the sharp freezer, allowing the sawdust and water to freeze into a solid cake. The water should be added slowly to prevent any possibility of water entering the sample containers. This method of packing will keep the sample in good condition for two or three days. Mark the shipping package "Perishable," "Rush." This notation should also appear on the shipping receipt.

Liquid egg products should be thoroughly mixed. Samples must be taken with sterilized instruments and placed in sterilized containers, preferably quart Mason jars. The precautions outlined for sampling frozen egg products must be observed. If it is impossible to deliver the samples to the laboratory on the day collected, they should be frozen and forwarded as previously indicated.

Shell eggs, wherever located, may be examined by candling. When decomposition is indicated, but not clearly evident under the candle, the eggs should be broken to determine their actual condition. The results of the examination should be reported to the station under an official I. S. number on the field egg candling report form (C. 471).

In commercial practice the following amounts are considered representative samples for candling:

In lots of 100 cases or less, candle one-half case from each of five different cases.

In lots of 100 to 300 cases, candle one-half case from each of eight different cases.

In lots of over 300 cases, candle one-half case from each of 10 different cases.

Where cases run uneven, or the lot consists of current receipts, candle a larger number of cases, and with small shipments of this class, candle from 20 to 50 per cent of the lot. In consignments made up of separate lots or grades, as indicated by different marks or branding, each lot and grade should be examined and reported separately. (See U. S. Dept. Agr. Bul. 565, "How to Candle Eggs.")

Bacterial Examination of Eggs. Much discussion has passed back and forth over the methods of egg analysis. The early methods were probably faulty, as Hadley has said, and data from the earlier work must be accepted with some reservation. Hadley has discussed the methods of analysis and any one interested in that subject should consult his work.

Poppe's³⁷ Method. The egg should be thoroughly cleansed with a brush and soap and placed for about one-quarter of an hour into 1-100 mercuric chloride. Then it is rinsed in sterile water and dried after treatment with alcohol and ether. Both ends are then punctured by means of a sterile needle and the egg placed in the neck of a sterile flask into which the white may run; a second sterile flask may be used to receive the yolk.

Kossowicz's⁶¹ Method. Wash the egg in 65 per cent alcohol and then flame the end which is to be opened. Rupture the shell with a sterile instrument and remove the contents with the aid of a sterile platinum needle, to suitable media. Kossowicz used a pair of sterile tongs for holding the egg.

Stiles and Bates'⁷ Method. The eggs should be washed in a solution of bichloride of mercury (1/1000) or 5 per cent phenol for a few minutes after which they should be dried with sterile cotton and placed with the large end uppermost in a small beaker. The air space is then scorched with a gas flame for a few seconds. An opening should be made immediately into the cavity with sterile forceps, a sufficient amount of the shell being removed without rupturing the membrane below. When this is accomplished the latter should be broken with a hot platinum spatula and with a sterile pipette .5 ml. of the white of the egg quickly removed and placed in the necessary Petri dishes for cultures. The remaining egg white is then decanted, leaving the unbroken yolk in the shell. With another sterile pipette, the yolk sac is ruptured and suitable portions of its contents removed for study. While this procedure guards against contamination, the breaking up of the respective layers of the egg when out of this shell is difficult, and sometimes the inability to do so interferes seriously with the obtaining of quantitative results. With the eggs which have been in cold storage for considerable periods a separation of the whites and the yolks is not possible.

Bushnell and Mauer's⁴⁰ Method. The egg should be cleaned with brush and soap and immersed for 10 minutes in a one to 500 solution of mercuric chloride. It is transferred with sterile crucible forceps to a small conical graduate, acute pole uppermost. The corrosive sublimate is removed and the egg dried by washing it first with alcohol and then with ether. The acute pole is scorched to kill spores, etc., that might remain. The egg is then immediately removed from the graduate by the operator holding it by the blunt pole, turning the acute pole down. The hands of the operator should have been thoroughly greased with vaseline to avoid contamination of the flasks by bacteria which might drop off the hands while handling the eggs. With sharp, stout forceps, which have been sterilized in the flame, a hole about one-half cm. in diameter is made into the acute pole. Holding the egg with the acute end down, and making the stab from below prevents contamination from above. The shell around the hole is flamed briskly and the egg is put with the acute pole upon the neck of a tall 300-ml. Erlenmeyer flask containing 100 ml. of sterile bouillon. The blunt end of the egg is heated with a Bunsen flame, while a close watch is kept on the hole. The heating expands the air in the air space and this expels the contents of the egg. As soon as about one-half

of the albumen has run into the flask the heating is interrupted. The cotton plug is quickly removed from a sterile flask, the neck of the flask is flamed and the egg is transferred from the first to the second flask. Sometimes it is necessary to invert the egg, as soon as the heating is discontinued, to prevent all of the albumen from running into the first flask. In this case it often happens that a little of the egg content runs down the outside of the shell, where it may become contaminated. To prevent such material from getting into the next flask, it is cemented to the shell by being heated in the flame. The expulsion of the albumen into the second flask should be done slowly and watched closely. As soon as the yolk appears in the hole the heating is interrupted and the egg is tilted from one side to the other to allow the rest of the albumen to run out. In the same manner the yolk is expelled in two portions. The success of this method depends largely on the size of the hole. If this is too small, it is hard to separate the white from the yolk; if it is too large, it is difficult to expel the yolk in two separate portions. Sometimes the yolk obstructs the hole before all of the albumen is obtained. If the yolk does not retract after cooling, the egg is inverted for a moment. Often the vitelline membrane will not rupture, and the yolk will come out in one piece. This can be prevented by puncturing the membrane with a sterile platinum needle. In this manner four flasks are obtained from each egg, two of them containing albumen and two of them containing yolk. The flasks are repeatedly shaken to mix the contents well. It is of advantage to have tall flasks because the contents can be mixed more easily without wetting the cotton plug. Two flasks, one with albumen and one with yolk, are incubated at 38°C.(100.4°F.) for 48 hours, and the other flasks are incubated at 20°C.(68°F.) for five days. After this period of development subcultures on agar slants are made to determine if growth has taken place.

Rettger's³⁰ Method for the Bacterial Examination of Eggs. The egg to be examined is placed small end up, in an egg cup or holder. The upper half of the egg is flamed with a Bunsen burner, the cup being turned constantly so that every part of the upper half of the shell is brought into brief contact with the flame. While the egg is held in the hand the upper end of the shell is removed with sterile scissors, leaving an opening about one inch in diameter. The white is poured out, care being taken to prevent it from running down the side of the shell. At this point the edge of the opening is flamed after which the entire yolk is poured out into a wide-mouthed flask, or better still, a large tube especially designed for this work by Rettger. Previous to introducing the yolk, definite amounts of nutrient bouillon are placed in the flasks (25-50 ml.) or tubes (25 ml.) which are plugged with cotton and sterilized. The yolk and bouillon should be thoroughly mixed. In case the test tube is used this process is greatly facilitated by the presence of a small glass rod about one and one-half inch in length. The tubes should then be placed in the 37°C.(98.6°F.) incubator and after 72 hours' incubation agar streaks made from them. These should be incubated for 24 to 48 hours.

Hadley and Caldwell's⁴¹ Method. The egg shell should be thoroughly disinfected before any opening is made. This may be accomplished by first washing the egg, if soiled, with soap and water and a wad of cotton, then immersing for 10 minutes in 1:5,000 mercuric chloride solution, containing either citric acid or ammonium chloride to increase the penetrating power. The egg may then be plunged into 95 per cent alcohol, removed, drained, and ignited to dry the surface. These operations can be carried on in a suitably constructed wire rack in which the eggs can await examination, being meanwhile protected from air contamination.

Next, as a final precaution, the egg should be well flamed at the end opposite the air space until a very thin layer (1-2 mm.) of the albumen lying close to the shell is coagulated. The amount of heating required can be ascertained by experience. After this, by means of sterile forceps, a hole about two cm. in diameter is made at the flamed end and the white poured into a tube or flask containing 25 ml. of the desired medium. Next, the opening in the shell is enlarged to about three cm. The yolk is allowed to run gently out of the shell onto a circle of sterile filter paper (kept in a small pile under the bell jar). The paper is then so inclined that the yolk rolls about until the white is entirely removed by the paper, after which the yolk is rolled off the

edge of the paper into a tube or flask containing at least 25 ml. of culture medium, an amount somewhat greater than the volume of the average yolk. Great care must, of course, be taken not to rupture the yolk membrane before the yolk is poured into the tube. The yolk may then be broken by means of a sterile glass rod and mixed with the broth.

The preparation is now ready for incubation which may be carried on for 48 hours at 37°C.(98.6°F.), followed by 48 hours at 20°C.(68°F.). The white may be mixed with the broth and grown in the same manner. At the end of the period of incubation the tubes should be again mixed by rotation to insure distribution of the bacteria, and a small amount on a straight needle transferred from each to ordinary tubes containing broth. The broth tubes are incubated at 37 and 20°C., as were the original tubes, and examined for growth at the end of four days. In case growth appears plate cultures are made.

It should be borne in mind that the recommendations made above are suitable only for fresh eggs in which it is desired to examine the yolk and white separately. In old market eggs, or preserved eggs in which the yolk is weakened, and in decomposed eggs in which the yolk and white have become mixed, different methods would be required; and here, as in the bacteriological examination of other egg products, the technique must be evolved in accordance with the particular aim of the investigation.

Schneider's suggestions on procedures for bacteriological examination of frozen eggs are given earlier in this chapter. They may also be applied to examination of other egg products.

Mustiness in Eggs. This characteristic of food products has usually been connected with molds, although the statements have not always been founded on laboratory data. Musty eggs have a very strong characteristic odor which is masked with difficulty by cooks and bakers. Turner¹¹¹ studied musty eggs and was able to isolate specific bacteria which caused the trouble. The yolks of such eggs appeared to be normal, but the white showed a definite opalescence suggestive of bacterial contamination. Direct microscopic examination made on the egg white showed numerous small gram-negative, somewhat bipolar cocco-bacilli. The microorganism was apparently present in pure culture. Turner believed it to be a new species and named it *Achromobacter perolens*. Turner was able to reproduce the spoilage using fresh normal eggs. His results seemed to indicate that the organism could easily penetrate the shell of eggs, especially those which had been washed. The same defect was encountered in the state of Iowa by Levine and Anderson.¹¹² Two new species and one variety of bacteria were described under the names: *Pseudomonas gaveolens*, *Pseudomonas mucidolens*, and *Pseudomonas mucidolens* var. *tarda*. Each of these organisms produced a strong must odor when inoculated into eggs. *Achromobacter perolens* was found to be the cause of an outbreak of musty eggs by Spanswick.¹¹³

Another odor defect of eggs, designated as a hay odor, was attributed by Hieronymi and Rodenkirchen¹¹⁴ to *Aerobacter cloacae*. Cultures of this organism infected eggs in five to six days; its growth limits were between 3°C.(37.4°F.) and 45°C.(113°F.) with the optimum at 30°C.(86°F.).

PATHOGENIC BACTERIA IN EGGS

Although eggs are not important causes of communicable diseases, they are known to occasionally harbor pathogenic bacteria. These reach the interior of eggs either by infection in the oviduct of the hen or by contamination of the shell after laying. It has been shown above that various microorganisms may penetrate the shell and that penetration is more rapid at high temperatures and humidities. A pathogenic, hemolytic *Streptococcus* was isolated from eggs by Trossarelli and Massano.¹¹⁵ Although Braga¹¹⁶ recognized the possibility of pathogenic bacteria in eggs, he was unable to isolate any member of the more well-known genera. Members of the genera *Escherichia* and *Salmonella* were isolated.

Mycobacterium Tuberculosis in Eggs. Since fowls are susceptible to tuberculosis, the question arises whether eggs from infected hens might be harmful. The organism which causes avian tuberculosis has never been considered to be of much significance for human beings. Fowls are not especially susceptible to human and bovine tuberculosis, although data are appearing that they may be more susceptible to the bovine type than formerly supposed. While the danger from eating eggs from infected hens may be remote, there is little reason for continuing the use of eggs from hens which are known to be infected. Fitch, Lubbehusen, and Dikmans¹¹⁷ have been studying this question from the standpoint of control of avian tuberculosis. Their results indicated that *Mycobacterium tuberculosis* was not transmitted through the egg. Poppe³⁷ had reported similar conclusions. None of the bacteria which he isolated from eggs were pathogenic. A different situation is indicated by results of experiments by Lichtenstein.¹¹⁸ She found *Mycobacterium tuberculosis* a sufficient number of times in market eggs to conclude that the danger of obtaining infected eggs on the market should not be underestimated. Lichtenstein also artificially infected eggs with *Mycobacterium tuberculosis* (avium). *Mycobacterium tuberculosis* (avium) was isolated from these eggs up to 167 days after infection and was demonstrable with the microscope up to the 198th day. Artificial inoculation experiments with the avian type of *Mycobacterium tuberculosis* of hens were made by Bonnet and Leblois.¹¹⁹ Eggs from these hens were examined for *Mycobacterium tuberculosis* for nine months. In view of the fact that no microorganisms were found, Bonnet and Leblois concluded that danger of avian tuberculosis in many was unlikely from eating eggs from infected hens.

Liverani¹²⁰ reported that *Mycobacterium tuberculosis* (avis) frequently passes into the reproductive organs and egg of the naturally or artificially infected fowls. Virulent bacilli of the mammalian types, both human and bovine, when intravenously injected into the fowl in large doses may be detected many days later in the same organs and the eggs. When 30 inocu-

lations of egg yolk had been made into culture media, eight, or 26 per cent, gave growth. All of the cultures inoculated with egg white were negative. Three yolks of six eggs from hens which died of avian tuberculosis gave pure cultures of *Mycobacterium tuberculosis* (avis). It is obvious that eggs may carry viable tubercle bacilli, the type determined largely by the contacts which the hen may have had.

Salmonella pullorum in Eggs. Pullorum disease is a *Salmonella* infection of fowls in which the eggs may harbor *Salmonella pullorum*. Other *Salmonella* diseases of fowls also result in the specific etiologic agent in eggs. This situation has caused some concern among health officers. Tittsler, Heywang, and Charles¹²¹ showed that practically every hen having ovarian *Salmonella pullorum* infection will eventually produce infected eggs. The actual percentage of such eggs is low but varies with the individual. Eggs artificially inoculated with *Salmonella pullorum* were to be completely sterilized only after five minutes' boiling. Somewhat similar results had been reported earlier by Rettger, Hull, and Sturgess.¹²² They gave some study to the presence of *Salmonella pullorum* in eggs from infected hens. They showed that eggs which were infected with *Salmonella pullorum* may produce abnormal conditions in young chicks and also when fed to young rabbits, guinea pigs, and kittens. In young kittens the symptoms were those of severe food poisoning owing to members of the paratyphoid group. Further interesting data were secured by these investigators in regard to the effect of cooking on the organism in eggs, though this may not always be the case. Their experiments showed that boiling or frying did not always sterilize the egg as far as *Salmonella pullorum* was concerned. Soft boiling, coddling, or frying on one side did not always render the egg yolk free of viable bacteria. These data show that eggs which have been put through some sort of cooking processes may not be safe for consumption and may be the cause of digestive disturbances. Andresen¹²³ believed that flocks could be kept from pullorum disease with care to sanitary conditions and infected birds.

Duck eggs, in the past few years, have been incriminated in food poisoning. Scott,¹²⁴ Charles,¹²⁵ Beller,¹²⁶ Clarenburg and Dornick,¹²⁷ Meissner and Kofer,¹²⁸ and others have published results of investigations. Scott reviewed some of the earlier literature and also reported results of his own experiments. Some of the outbreaks of food poisoning resulted from infections of custards with *Salmonella* species in the eggs. Meissner and Kofer described an outbreak of food poisoning affecting 50 guests at a wedding party. Fromme¹²⁹ reported numerous outbreaks which were caused by duck eggs which had been used in preparation of potato salad.

Salmonella enteritidis and the Breslau bacillus were isolated. Numerous other outbreaks have been reported which have to be left for review in the author's book, "Food-Borne Infections and Intoxications." In Germany laws have been passed which compel prominent labeling of duck eggs when offered for sale.

Lichtenstein's¹¹⁸ Method for Determining the Presence of *Mycobacterium tuberculosis* in Eggs. The egg is well washed with soap and hot water and then rinsed with sterile water and absolute alcohol. It is then punctured at both ends with a sterile glass rod, one end placed over the mouth of a glass measuring cylinder, and the contents allowed to flow into the cylinder. Four or five eggs are used in each preparation and the volume of egg mass measured. The egg mass is next mixed with a three-per cent solution of antiformin either in a mortar with glass beads or otherwise. Six parts of antiformin are used to one of egg. The mixture is then placed on a mechanical shaker so that a homogeneous mixture is secured. The material is then centrifuged at 3,500 to 5,000 r.p.m. for about 30 minutes. The sediments from the tubes are then centrifuged again in physiological sodium chloride solution, washed, and re-centrifuged three times. The supernatant liquid is poured off and the sediment used for examination. Films may be stained and cultures made in suitable culture media. Lichtenstein used Petragnani's medium which he had found to be the best. Undoubtedly other modern media would be just as satisfactory.

CHAPTER 23

MICROBIOLOGY OF CANNED FOODS

Preservation of foods in sealed containers, commonly called canning, is a great industry in the United States. While canning is generally practiced in factories located as near the source of raw products as possible, it is also done in the homes of America. The great problem is to preserve foods in such a manner that they are as near like the fresh products as possible, to preserve their nutritive qualities, and to rid them of microorganisms which spoil them or make them deleterious to health.

The history of the preservation of foods by canning is rather extensive and goes back to a remote experimental period in the development of microbiology. Indeed, some of the early investigations in fermentation were really attempts to preserve foods in hermetically sealed containers. Probably the first experimental work which had bearing on the subject was conducted by Needham, who attempted to preserve various organic materials by heating them in closed containers; since they did not keep, he assumed that life had developed spontaneously. It remained for Pasteur to discredit this explanation.

In 1795, the French government did much to stimulate the preservation of foods by offering a prize of 12,000 francs for the most satisfactory procedures. In 1810, the French Minister of the Interior awarded the prize to Nicholas Appert, a man who, as a pickler, fermentologist, and confectioner, had gained much experience in the care and preparation of foods. His book, *The Art of Preserving Animal and Vegetable Substances*,¹ ran through four editions the first of which appeared in 1811. The real significance of Appert's inventions was not realized until after his death. Appert's son was then made a Chevalier in the Legion of Honor to atone, in part, for the lack of recognition accorded his father. This early work was carried out in France and we may regard the canning industry as having originated in that country. The utensils which Appert used were crude when compared with our present-day equipment.

Appert did not explain the fundamentals upon which his methods rested, although elimination of air and application of heat were believed to be important factors. So many different theories were proposed that the French government appointed Gay-Lussac to investigate the matter. This scientist stated that decomposition was caused by the presence of air, and that if air were driven out, no oxidation could take place. The discovery of microorganisms, however, rendered this theory untenable. Pasteur, in 1860, proved that decomposition was caused by microorganisms and that, to control food spoilage, other things than presence of air must be considered.

1. Appert's manual, "The Book for All Households, of the Art of Preserving Animal and Vegetable Substances for Many Years," has been translated from the French by K. G. Bitting. Glass Container Association of America, Chicago, 1920.

Appert's first problem was to find a container in which materials could be preserved after they had been sterilized. He finally chose one made of glass.

In 1810, an English tin plate worker by the name of Peter Durand was granted a patent by the English government. While he was probably not the originator of the process, his work did much to stimulate interest. About the same time, a Mr. Saddington read a paper before an English society on "A Method for Preserving Fruits Without Sugar for House or Sea Stores." The method proposed by Saddington resembled very closely the modern cold-pack process. Pierre Antoine Angilbert, a Frenchman, probably made the first real advance in the perfection and use of tin cans for food preservation. After the fruit had been placed in a can, a piece of tin with a small hole in it was soldered on the can. After the process the hole was tipped with solder.

In America, Thomas Kensett was the first to use the tin can in food preservation. He packed various sea foods, such as salmon and oysters. At this time cans were hand made and a great amount of time was consumed in their manufacture. In 1839, Winslow attempted to pack corn in Maine. He applied to the United States government for a patent which was granted in 1862. The Civil War did much to hasten the day of canned foods. Winslow was a whaler and saw the suffering from scurvy to which sailors and others on an inadequate diet were susceptible. Canned fruits and vegetables were desired to supplement the monotonous diet supposed to cause scurvy. The history of canning is covered in a number of publications, notably those of Judge² and Bitting.³

How Long Will Canned Foods Keep? If all microorganisms in a can of food are destroyed and the ingress of others prevented, canned foods should keep indefinitely, so far as microorganisms are concerned. Slow chemical changes, however, may render the food inedible. One case is on record where tinned food remained edible for 90 years. Corned beef and pea soup were brought back from an arctic depot where they had lain for 86 years. In another case, canned peas which had been mislaid for 24 years were edible. In the *Canner* for April, 1927, are recorded the results of the examination of a can of beef which was 81 years old. A similar report in the same journal for October 5, 1929, records observations on canned meat and milk over 35 years old.

Canned foods of historic interest have been examined in a thorough manner by several groups of investigators.⁴ They examined the foods from all angles. Only the investigation by Wilson and Shipp, which was bacteriological in nature, need be reviewed here.

A can of Parry's "Roast Veal," canned in 1824, yielded on very careful examination, three strains of sporeforming anaerobes which had remained viable for over 100 years. Similar examination of a can of Libby's

canned tripe, packed in 1880, and a can of carrots packed in 1885, yielded completely negative results.

General Sanitation of Canning Plants. The food packer, by using clean materials and handling them in a cleanly manner, will greatly reduce the load on the sterilizing process which he is using. The practical phases of the question were discussed by McMeans.⁵ Cleanliness and general sanitation have a real monetary value to the canner. As is stated elsewhere in this chapter, the procedures used in canning each food are founded on conditions which obtain in the average canning factory. They include both raw materials in the average state of freshness and average apparatus. If, by using careless unsanitary procedures, the average process times and temperatures are overloaded, many of the cans will not be sterilized and the contents will later spoil. Aspects of the problem from the viewpoint of the Food and Drugs Act are reviewed by Linton.⁶ The main object of high sanitary standards is a high-quality canned food. White⁷ discussed the general examination which could be given the can itself. Savage⁸ believed that canned foods were definitely less liable than ordinary foods to be a source of food poisoning.

GENERAL PROCEDURES IN CANNING

No one set of procedures can be used with all foods. Some foods require more washing or special preliminary treatment. In the following paragraphs a few of the basic procedures which are used with many foods are discussed.

Raw Materials. If the finished product in the can is to be high grade in every respect, the raw materials must be the best that can be secured. For this reason and not alone on account of expense, canning factories are located near the source of raw materials. Many vegetables lose their fresh appearance and taste soon after harvesting. Beans become tough and stringy. Fruits become soft and the skins broken, making them susceptible to the attack of microorganisms.

Preparation. The procedure followed depends entirely on the product. It is obvious that a different method must be used for peas than for strawberries. Lima beans must be threshed from the vines and graded. Corn is usually cut from the cob after careful inspection. String beans must be snapped, and some fruits must be pitted.

Grading. Some foods packed in tin cans are not graded, while with others the practice is carried to extremes. There are, for example, some 25 or more grades of peas and many grades for other foods.

Washing. Most foods to be preserved by canning are thoroughly washed. The methods which are used depend on the type of food as well as the type of soil on which it is grown. Some vegetables grown in sandy soil require less washing than those grown on clay soils. This is not always the case,

however. Washing probably removes many bacteria which would otherwise have to be destroyed later by the process.

Scalding or Blanching. Many fresh foods are scalded or blanched early in the canning procedure. Magoon⁹ tabulated the following reasons:

1. Removal of substances which give undesirable flavors to the canned product.
2. Improving the color of the cut-out material by bringing the color to the surface where it is "set" or "coagulated" by the subsequent treatment.
3. Removal of mucilaginous substances from the raw materials.
4. Shrinking and softening of tissues facilitating a full container.
5. Production of clearer liquor in the can.
6. Destruction of bacteria thus lightening the load on the process.

Considerable attention has been given to the effect that blanching might have on the bacteria. Probably most of the nonsporeforming bacteria would be greatly reduced in numbers while the sporeformers might not be greatly harmed. Magoon stated that the water of the scalding bath might, at times, contaminate the food, provided it was used over and over again. This is especially true for the thermophilic bacteria, as shown by Cameron¹⁰ in his experiments to find the origin of spoilage organisms.

Bushnell¹¹ reported that blanching was of no value in reducing the time necessary for processing canned foods. The results of Bushnell's experiments should probably not be applied to foods packed under commercial conditions. The same question was studied by Bruett,¹² who stated that spores of bacteria were not made more sensitive to heat by sudden chilling. In the "cold-pack" process, blanching was found to have no bacteriological justification on the grounds of increased susceptibility of the bacteria to heat because of cold shocks. Blanching was said, however, to have a cleaning action. Undoubtedly, many nonsporeforming bacteria are killed, but blanching as such does not possess great advantages as far as the process is concerned. Burke¹³ also found that blanching had no effect on the spores of resistant sporeformers.

Exhausting for Vacuum. The object of the exhaust in canning practice is to force air or gas out of the can by having the contents of the can as hot as possible before closing. If the can is sealed while it is hot, a vacuum will result when it cools. With some foods which permit very slow penetration of heat, it is often necessary to tip the can under vacuum. The gas in a can of food comes from entrained air in the food and air in the head space. It is the oxygen in this gas which causes considerable trouble with some food products. Clark, Clough, and Shostrom¹⁴ of the National Canners Association have presented the theoretical and practical significance of vacuum. Other discussions of the same subject have been prepared by Daughters¹⁵ and Gray.¹⁶

Exhausting was apparently practiced quite early since it was believed that a vacuum was necessary to make foods keep. Appert believed that oxygen should be removed. It is now known that vacuum in itself has little relation to bacterial spoilage. It may influence, to a certain extent, the types of bacteria which may develop in that a poor exhaust will leave more oxygen in the can, but the direct effects of vacuum are not significant. However, it does play a role in chemical spoilage to which the canned foods are susceptible.

Adam and Stamworth¹⁷ have stated that the vacuum which occurs on cooling a can below its closing temperature is primarily caused by changes in vapor pressure and partial air pressure. The effect in both cases increases with the closing temperature and that due to partial air pressure is kept at its highest value by the prevention of cooling of the head space between exhaust and closing. This may be best achieved and controlled by clinching the cans before exhausting. The causes of change in the vacuum on storage are discussed and new methods of vacuum measurement and their limitations were described.

Some of the foods preserved by canning contain large amounts of air. Data were published on this subject by Culpepper and Moon,¹⁸ as well as by Baker¹⁹ and Clark.²⁰ Exhausting serves to remove some of this air. If the exhaust time is not right, gases entrained in the foods themselves are not removed, vacuum in the can may be lowered, and more trouble from corrosion and perforation may result. Insufficient exhausting will also cause flippers since the vacuum will not be great enough to hold the ends of the can in.

Various methods are used in practice for obtaining an exhaust in canned foods. Some are more applicable to certain foods than to others.

Exhausting by Heat. This is the oldest and under many conditions the best method for getting the air out of the can. The period of exhaust and the time required depend on the food. Certain foods, such as sweet potatoes and meats allow such slow heat penetration that it is necessary to place them in the cans while quite hot. It is almost impossible to secure sufficient heat at the center of the can. Bigelow and his colleagues at the Research Laboratories of the National Cannery Association found slower heat penetration with these foods than with any foods studied. The absence of convection currents probably explains it.

Exhausting by Mechanical Means. By this method the cans are closed in a chamber in which a high vacuum is maintained. This method has been used for many products packed in glass and more recently has been applied to vegetables and fruits in tin containers.

Clark, Clough, and Shostrom¹⁴ gave the following reasons for obtaining a vacuum in canned salmon. These probably hold equally well for other foods in tin containers.

1. To keep the ends of the can flat or collapsed. This is important since one important criterion of a satisfactory can of food is the condition of the ends. Cans with flat concave ends are usually satisfactory although some types of spoilage are not

accompanied by gas formation. Bulged ends may be due to lack of vacuum or generation of hydrogen.

2. To reduce the strain on the cans during processing. When the sealed can is processed in the retort considerable pressure is developed. Cans which enter the retort with a good vacuum will have the lowest pressure produced during cooking in the retort.

3. To restrict or prevent growth of certain species of bacteria. The removal of oxygen prevents the growth of aerobic bacteria—those which grow best in the presence of free oxygen.

4. To prevent undesirable changes, such as destruction of accessory substances, and to reduce the chemical reactions between the container and its contents.

Factors Which Influence the Vacuum in Canned Foods. The vacuum which a can will have depends on a number of factors. These have been discussed numerous times in the literature. Clark, Clough, and Shostrom¹⁴ later summarized them as follows:

1. *Time and temperature of exhaust.* The vacuum attained in a can will depend certainly on the temperature. This is in turn dependent on the time that the can is heated. The higher the temperature to which the can is heated, the more vapor is formed to condense in the sealed can.

2. *Fill of the can and head space.* The head space is made up of air, the oxygen in which, will be slowly used up producing a vacuum.

3. *Exhaust with cans open or with lightly clinched covers.* In the salmon industry, according to Clark *et al.*,¹⁴ better vacua are secured with the covers loosely clinched. There is better retention of heat. This may also be due to steam getting into the can to replace the air.

4. *Delay between exhaust box and closing machine.* Any delay here will cause a loss of heat and will thus negate the exhaust.

5. *Loose or tight seams.* In order to hold a good vacuum the seams of the can must be tight. Loose seams may allow air to escape in the retort and the seams may close after the can has left the retort. Some cans of vacuum packed food show a vacuum of 24 inches.

6. *Fresh or stale foods.* Clark, Clough, and Shostrom found that stale salmon caused more carbon dioxide in cans than fresh salmon. In the retort most of this carbon dioxide is driven into the head space.

7. *Use of heavy tin plate having several expansion rings.* Cans with heavy plate in the ends will not be pushed out easily. This factor, strictly speaking, does not influence the vacuum but the can will possess flat ends. Such a can will also resist changes in appearance owing to gas formation by bacteria or to atmospheric conditions.

8. *Altitude.* Springers may result from altitude even though the contents of the cans are satisfactory. Low vacuum cans usually become springers at high altitudes.

Vacuum itself probably has very little effect on microorganisms. The few reports which have been made on this subject indicate that bacteria may live for long times in vacuum. Some of the species with which Brown²¹ worked were alive after five years in vacuum. Lowering of the temperature, along with vacuum, apparently increases the longevity of bacteria. Bitting²² reported that vacuum of 25 inches did not check the development of yeast or *Oidium lactis* but did check that of *Aspergillus* species. While vacuum does not have much influence on the microorganisms, it has become a very important factor in canning. Gas-forming bacteria tend to reduce vacuum in a tight container in which they are able to grow.

Maclinn and Feller's²³ Method for Determining the Vacuum in Glass Jars. Two methods were proposed for determining vacuum in all-glass jars used in the preservation of foods.

21. Brown. 1932. *J. Bact.* 23, 34; *Abstr. Bact.* 9 (1925), 8.

22. Bitting. 1925. *The Canning Age*, April, 1925, 413.

23. Maclinn and Fellers. 1936. *Food Research* 1, 41-44.

Vacuum-Desiccator Method. A large vacuum desiccator is connected with pressure rubber tubing to a vacuum pump. The connections should be tight so that a vacuum of 27 to 29 inches can be attained. An ordinary Chapman water pump attached to the water faucet will usually answer the purpose. The jar of food, vacuum in which is to be determined, with clamps removed is immersed in an open glass container with enough water to cover the jar. This container with the immersed glass jar is then placed in the vacuum desiccator. The lid is replaced and the stop cock opened. A vacuum gauge should be placed in the line to indicate the vacuum. The air is slowly exhausted. When the vacuum inside of the desiccator exceeds that in the jar, the glass cover will lift and bubbles escape. The vacuum gauge should be read at this instant. Some difficulties may be encountered if the jars have been packed a long time on account of the rubber rings sticking to the glass.

Water-Displacement Method. This method depends on displacement by water of a certain volume of the head space, depending on the vacuum (partial pressure) present in the jar. The jar is weighed after processing; this weight includes the complete container and contents. The jar is then immersed in water in an inverted position and the seal broken, which permits the head space to fill with water in proportion to the vacuum in the head space. Still holding the jar inverted, the water levels inside and outside the jar are made the same, the cap is replaced, the clamps tightened, and then the jar is removed from the water, wiped off, and weighed. The difference in weight between the second and first weighings gives the amount of water sucked in. The lid is then removed and the jar completely filled with water, including the volume under the glass cover. This weight minus the first weighing gives the volume of the head space, and from the weight of the water sucked in, the vacuum can be calculated. The technic is very simple. An example is given:

(a) Weight of the jar and contents after processing.....	980 gm.
(b) Weight after opening under water.....	1,030 gm.
(c) Gain in weight (b—a).....	50 gm.
(d) Weight of jar and contents completely full.....	1,050 gm.
(e) Original head-space volume (d—a).....	70 gm.
(f) Vacuum $\frac{(b-a)}{(d-a)} \times 30$	21.4 inches.

HEAT PENETRATION IN PROCESSING CANNED FOODS

Few of the earlier workers in the field gave attention to the rate of heat penetration into various food products preserved by canning. Prescott and Underwood,²⁴ who attempted to follow the temperature changes in cans of corn by sealing registering thermometers in the cans, observed that, regardless of the retort temperature, the temperature of the can reached it in the same time. This has been observed by others since then. Belser,²⁵ working on a number of common fruits and vegetables, observed considerable variation in the time required to come to retort temperature. Studies by the National Cannery Association (Bigelow, Bohart, Richardson, and Ball²⁶) culminated in an extensive report dealing with most of the common fruits and vegetables packed in tin cans and glass. The older methods of working, involving the use of thermometers, were replaced by those in which thermocouples were used. The use of this apparatus has made it possible to follow the temperature change at the center of a can which is being processed under ordinary conditions. Magoon and Culpepper²⁷

also published the results of studies of the rate of heat penetration into various canned foods.

Factors Influencing Rate of Heat Penetration Into Canned Foods. Several factors, as would be expected, influence the rate of penetration of heat into canned foods. The investigators in the Research Laboratories of the National Canners Association have stated some of them as follows:

1. *Shape and size of the container.* It is apparent that a large can of food would require longer to come to retort temperature than a small one. This is due to the fact that heat has further to travel from the outside to the center of the container. Larger cans also have less surface in proportion to the volume than smaller ones.

2. *Consistency of the food product.* A food product with considerable free liquor would allow more rapid penetration of heat than one which is solid or viscous. This is well indicated by curves which have been published by the National Canners Association as well as by Magoon and Culpepper.²⁷ The latter investigators started their studies on heat penetration by using distilled water in No. 2, No. 3, and No. 10 cans. In No. 2 cans the temperature of the bath was reached in about nine minutes, the No. 3 can being only slightly slower than the No. 2. The No. 10 can required 10 minutes. Studies were also made with brine and sugar solutions to see whether the addition of these materials had any effect. Salt had little effect as did dilute sugar solutions. Concentrated sugar solutions, however, had considerable effect in retarding penetration of heat. One, two, three, four, and five per cent starch solutions were also studied. The curves which graphically showed the results indicate a progressive inhibition to heat as the concentration of starch is increased. The differences between one, two, and three per cent solutions were not great, however, but they did exist.

3. *Reaction of the food.* This is offered as one of the factors influencing heat penetration. It is probably of less importance than other factors.

4. *Location of the can in the retort.* Bigelow and his colleagues, Bohart, Richardson, and Ball,²⁸ observed that with corn, cans at the center of the crate heated as rapidly as cans at the outside. Furthermore, no difference could be found between cans which were thrown into the crates promiscuously and those which were stacked solid. The situation was different with milk. The cooker must contain steam only under pressure. If mixtures of air and steam obtain in the cooker, the pressure on the gauge will not indicate the actual temperature. In order to avoid air pockets in cookers, canners allow a little steam to escape during the cooker process, a procedure known as "bleeding." It keeps the steam moving in the retort.

5. *Agitation.* Cooking in agitating cookers permits more rapid penetration of heat with some foods. The cans may be rotated on their axis or they may receive irregular agitation.

6. *Initial temperature.* The can should be as hot as possible when it enters the retort. Many investigators have stated that cans at lower temperatures will heat faster in a retort than cans at higher temperatures. The important factor, however, is the time that the can is at retort temperature, for it is this temperature which causes the greatest reduction in the number of viable cells. It has been shown that cans heated to different temperatures and placed in a retort and processed together will reach retort temperature in the same time.

7. *Temperature of the retort.* It is obvious that this factor will have a bearing on the rate of heat penetration into cans.

Discussion of methods for determining heat penetration is outside the scope of this book. The subject is covered by Magoon and Culpepper,²⁷ Ball,²⁸ Bigelow *et al.*,²⁶ and others.

Slope of the Heat-Penetration Curve. Heat-penetration curves are plotted from results of observations on temperature changes at that area in the can of food which is heated most slowly. Such results are usually

28. Ball. 1923. Natl. Res. Council, Bull. 7.

secured with thermocouples. Even though the efficiency of the process is largely determined by the rate of penetration of heat into the can, accurate information on the subject came rather late in the development of canning technology. Those who desire to read into the subject should consult the papers by Bigelow, Bohart, Richardson, and Ball²⁶ and Ball.²⁹ In these publications many curves for the rate of heat penetration into many different foods may be consulted. The ideal situation would be to have a curve for every food in the various sized containers under all of the various methods of packing. The great amount of work which would be involved prevents this. Consequently, canning technologists have been driven to calculation of heat-penetration curves for some foods. The procedures may be secured from the bulletins mentioned above, but especially from a publication by Ball.²⁹

STERILIZING PROCESSES

This is the step in which attempt is made to destroy microorganisms which may later spoil canned foods. It has been defined by the National Canners Association³⁰ as the heat treatment expressed in terms of temperature and time given the product after the container is permanently sealed.

Ball²⁸ stated that the object in processing canned foods is the attainment of sterility with respect to the most resistant microorganism present which would cause spoilage. Some have distinguished between the terms processing and sterilizing. Sterility is the ideal toward which canners strive, but which is not easy to attain with some foods without harming the quality. Some processed foods may contain heat-resistant spores, such as those of thermophilic bacteria. Some such spores have been shown to resist over 20 hours' boiling and to withstand the maximum process times and temperatures regarded as satisfactory. To absolutely destroy such resistant spores might render the food unsuitable for sale.

Consequently, some canning technologists have modified the term "sterilization" to indicate the bacteriological condition attained in some foods by processing. Since the term "sterilization" implies the absolute destruction of all living organisms, and since this condition may not be attained in some processed foods, the term "commercial sterilization" has been introduced. The term indicates the condition of some processed canned foods in which viable spores exist. The contents of the can remain commercially sound as long as the cans are properly handled. In this manner, the results of sterilization procedures (complete sterility) are distinguished from the results of processing (commercial sterility). Closely connected to this discussion are the methods of determining sterility. Though it would be possible to destroy any number of resistant spores in a can of food, the food might be so changed that it would be unfit for sale. Ball³¹ prepared a fine review, mostly along historical lines, which should be read by those who are trying to secure a complete picture of sterilization methods for

31. Ball. 1938. *Food Research* 3, 13-55.

canned foods. The object of processing, then, is not so much the complete sterilization of the food as it is to make it keep and be wholesome.

Several methods are used for processing canned foods. Two general methods are most commonly used—dry steam and hot water. Since there was considerable difference in opinion among canners over the efficiency of these methods, the National Canners Association made numerous tests with several kinds of products cooked by both methods. The results, reported by Bigelow *et al.*,²⁶ showed no difference in rate of heat penetration whether processing was done in steam or hot water (under steam pressure).

Continuous cookers have been introduced in recent years and found to be satisfactory with some foods. In these cookers the cans are rotated, a factor which, with many foods, speeds up heat penetration. Such cookers are used in the processing of canned milk. The introduction of the continuous cooker is the result of effort to introduce rapid mechanical features into the process procedure. These cookers are cylindrical shells placed in horizontal position (Flannery³²). Inside the cooker is a helical runway for the cans of food. On this runway the cans progress from the intake end to the outlet end. The cans enter and leave the cooker through valves so constructed that the can is introduced and released from the cooker without altering greatly the conditions within the cooker. These cookers are operated at such speeds that every can receives the same heat treatment. The cans are passed to a mechanical cooler when they leave the cooker.

Principles Involved in Processing. The process may be considered to be disinfection by moist heat and probably subject to the laws of disinfection. Since the rate of disinfection is an orderly time process and dependent upon the number of living cells present, it is obvious that the canner should keep the microbial load in his product as low as possible. The fewer the bacterial spores the easier is processing. Process times and temperatures are based on average contamination. Duckwall,³³ in the early days when attempt was being initiated to apply scientific principles to what had been generally the art of canning, recognized the value of reducing contamination to the minimum. Actual laboratory investigations by Esty and Meyer³⁴ showed beyond dispute the effect of increasing numbers of spores on the amount of heat required to destroy them. Larger numbers required more heat for destruction. Hallman and Stevenson³⁵ stated the following as being involved in determination of a process for any canned food:

1. Determination of the thermal death time of heat-resistant spores of the spoilage organism with which the food might become contaminated under commercial conditions.
2. Determination of the rate of penetration of heat into the can of food under consideration.
3. Calculation of the theoretical process from the thermal death time and heat-penetration data.
4. Checking the theoretical process by processing inoculated cans and incubating to determine whether the inoculated microorganism has been destroyed.

32. Flannery. 1929. Food Indus. 1, 651 and 694.

33. Duckwall. 1905. Canning and Preserving of Food Products.

34. Esty and Meyer. 1922. J. Inf. Dis. 31, 650-663.

35. Hallman and Stevenson. 1932. Ind. Eng. Chem. 24, 659.

It is necessary to know the maximum resistance to heat of spores of spoilage bacteria as well as of those which might render the food hazardous to health. In the latter category falls *Clostridium botulinum*. Many investigations have been carried out to learn more about heat resistance of *Clostridium botulinum* under conditions simulating those in canned foods. The well-known publication of Esty and Meyer³⁶ gave maximum resistance of spores of *Clostridium botulinum* in standard phosphate solution at different temperatures.

One of the more recent attempts along these lines is that by Townsend, Esty, and Baselt³⁷ who worked with a sporeforming anaerobe which produced spores having a high heat resistance (No. 3679 isolated by Cameron³⁸) and several strains of *Clostridium botulinum*. The details of their experiments need not be reproduced here. They concluded that heat resistance of *Clostridium botulinum* is different in canned foods than in neutral phosphate solution. Heat-resistance characteristics of anaerobe No. 3679 were found to be unlike those of *Clostridium botulinum* in food media but were similar in neutral phosphate solution.

Factors Influencing Processing. Processing is influenced by many factors. It should not be looked upon as the mere application of heat to a food in a closed container. If this were all that is involved, less bacterial spoilage would occur and the canner could easily sterilize the food by using a sufficiently long process time. However, the quality of the food has to be considered. Probably the two factors which rule more than others in the selection of process times and temperatures are quality of food and under-sterilization. Under the latter term is included, of course, the effect of heat on spores of *Clostridium botulinum*. Canners have to face the question of having safe cooks or processes.

Among the various factors which may affect the sterilizing value of the process, Bigelow³⁹ listed the following:

1. The initial temperature may be too low.
2. The contents may be too closely packed.
3. The accuracy of the retort thermometer.
4. The amount of care exercised in holding the retort thermometer at the desired temperature.
5. The "coming up" time of the retort.
6. The influence of the temperature control apparatus on the "coming up" time and initial temperature of the retort.
7. The size and shape of thermometer pockets.
8. The amount of venting and the position of the vents.
9. The construction of the retort, especially the distributing system on steam pipe.
10. The amount of water in the retort during processing.
11. The manner in which very small cans are stacked in the retort.
12. The manner of cooling the product and the promptness with which it is cooled after processing.

The hydrogen-ion concentration of the food product has much to do with the efficiency of the process. Bigelow and Cathcart⁴⁰ discussed its

40. Bigelow and Cathcart. 1921. Natl. Canners Assoc. Bull. 17-L.

significance in processing canned foods. From their work, it is evident that fruits have an acidity greater than that represented by pH 4. In general the process required decreases as the food products are more acid. The few exceptions, however, were suggested to be due to heat penetration. Some foods with a hydrogen-ion concentration which suggests a high process may require a short one. Peas, for instance, might appear to need a longer process than other foods of the same hydrogen-ion concentration. Heat penetration, then, seems to be more important than hydrogen-ion concentration in processing. Processing itself tends to raise the hydrogen-ion concentration of certain foods.

Another factor of importance is presence of sugar or heavy sirups. At various places in this book, the slowing effect of these on destruction of bacteria by heat has been discussed. Here an instance in the canning industry will be mentioned. It was conceived that when sugar needed to be added to a product about to be canned that it could be added as such to the can before the food was put in and that it would distribute itself throughout the can during the process. Braun, Hays, and Benjamin⁴¹ found that this was not the case. Dry sugar was found not to dissolve but to form strata of sugar sirups in the container. These retarded heat transfer to the interior of the can. Consequently foods sweetened with dry sugar, may require more drastic heat treatment than foods sweetened with sirups.

Vacuum Processing of Canned Foods. A few years ago a method of packing and processing foods was introduced without water or brine. It was spoken of as "waterless processing" or "vacuum packing." The vegetables are filled into the can, the air is removed by a vacuum pump or replaced with steam before sealing or processing. Many foods canned in this manner are superior both as to appearance and flavor as well as keeping quality. Vacua of from 20 to 27 inches are attained immediately after closing. Such foods seem to be more easily sterilized. Tanner and McCrae⁴² found that spores of *Clostridium botulinum* were more easily destroyed when heated in tubes in which the vacuum had been reduced to 17 mm. before closing. Konrich⁴³ carried out experiments on the effect of vacuum on the temperatures required for processing meat in cans. In no instance was he able to show that exhausted cans were more easily processed. His conclusions are probably applicable only to the conditions under which he worked.

Control of Processing. More is involved in processing than merely making canned foods keep. They must be safe. Soundness of a can of food does not necessarily require that the product be sterile in the surgical sense. It is not a question, according to Esty⁴⁴ whether viable bacteria are present but whether the food is wholesome.

44. Esty. 1935. Amer. J. Pub. Health 25, 165-170.

Processing is, in general, not under active control by official groups. Relation of certain canned foods to botulism prompted the California State Department of Public Health to attempt to give this important step in canning official supervision. Canning inspection started in 1920 under jurisdiction of the Bureau of Pure Food and Drugs. After 1920, more and more supervision was given this work until finally, in 1925, an act was passed and approved by the governor creating a Division of Cannery Inspection to regulate canning. Important in this effort to pack and market wholesome canned foods is coding of cans. This makes it possible to identify any lot of questionable quality and segregate it if necessary. In addition to the type of control mentioned above is that involving laboratory analysis of the contents of the can. Esty reviewed the problems involved. He emphasized the complexity of determination of causes of spoilage.

Experimental Determination of Processes for Canned Foods. In the earlier days when canning was more of an art, processes were arrived at by experience. Each canner used times and temperatures which he thought were satisfactory and used them as long as little spoilage resulted. It was a trial-and-error method and was based on natural contamination which at the time may have been low. When his product was more heavily contaminated, the spoilage which resulted prompted him to make adjustments usually increasing the process. Only rarely could a packer make some of the determinations which are regarded as necessary. Williams⁴⁵ mentioned them as measurement of heat penetration, inoculation with a selected test spoilage organism, calculation of a final process, and checking it with experimental packs. Processes are calculated by a formula of Ball²⁹ involving heat-resistance data on test bacteria and heat-penetration data on the food in the can. This is the theoretical process.

Good results in processing depend on adequate penetration of heat to that part of the can which heats most slowly as well as the heat resistance of spoilage bacteria most likely to spoil the food in question. If the food happens to be one in which food-poisoning bacteria may develop, they must also be considered, especially the arch enemy of the canning industry *Clostridium botulinum*.

Cameron⁴⁶ has described a series of experimental packs involving corned beef hash and potted meats. Those who desire specific details of Cameron's work may consult the original report. Only the general features of the experimental pack need be given here. In such work it is necessary to have very resistant typical bacteria with which to inoculate the food. If corn is being packed it may be inoculated with the spores of a resistant thermophile, such as No. 1518 described by Cameron and Esty.⁴⁷ The heat resistance of this organism can be easily determined. In the experimental packs with meat products, Cameron finally secured a putrefactive anaerobe which had a heat resistance of 12 hours at 100°C.(212°F.). This organism was added to the corned beef hash and potted meat. After the organism has

been added to the food product, it is canned and processed at the calculated times and temperatures. The cans are then stored under conditions which will cause spoilage. In this manner, it is possible to check the theoretical process with the actual results obtained when it is used. Before the days of research laboratories, each canner had to make his own experiments. He usually used those process times and temperatures which gave the least spoilage. Now the processes are based upon carefully carried out experiments and are no longer secured by trial and error.

Much discussion has occurred on the method that shall be used for incorporating the test bacteria in the food and the type of inoculum that shall be used. The object is to secure spores of representative resistance and place them in that part of the can which will probably receive the lowest heat treatment. That, of course, may be the center. Little information of value would be secured by filling the can and placing the organism on the top just under the cover. The only satisfactory method is to mix the spores with the food before it is filled into the cans. This is not difficult with such foods as peas and corn but requires special attention in the case of meats, fish, and sweet potatoes. In the case of meats which are in fine pieces or ground, the spores may be incorporated while the meat is being stirred in a mixer. The spores should be thoroughly incorporated in a small amount of the food and this inoculated portion added in small portions to the entire batch. In this manner, the spores will be distributed as nearly as possible as they are in natural infection. It is more difficult to incorporate the test organisms in such materials as ham, fish, and sweet potatoes. In this case, the organisms may be carried on pieces of thread which may be placed in the can where the bacteria are desired. The practice of putting the bacteria into one place in a can by means of a pipette is to be questioned. Such a procedure may place too many bacteria at one place.

Another question which has to be settled is the type of inoculum. Shall it be dry soil or an aqueous suspension of spores? In Chapter 2, the methods for preparing spore suspensions used in recognized procedures for determining thermal death times are given. These are, in general, pure-culture suspensions. Since these methods were devised, some have suggested that the test bacteria could be carried in soil which has not been sterilized. These suggestions originated in the desire to secure an inoculum as near a natural one as possible. Since opinions are not yet in agreement on these problems, the various methods of inoculation will not be discussed further.

It is also necessary in experimental packs to select the proper test organism with which to inoculate the food. This selection is usually made from studies on causes of spoilage of the product under consideration. It is necessary to know the nature and type of spoilage likely to occur when the food is underprocessed. Williams⁴⁵ reviewed this problem. As a result of extensive heat-resistance studies and types of spoilage caused by them, the following test organisms have become important and have been used in many experimental packs.

1. *Clostridium sporogenes*, strain No. 3679, with a heat resistance in excess of the maximum recorded for *Clostridium botulinum*. This is used

for nonacid products and in some cases for semi-acid products. This organism is a *putrefactive anaerobe*. Cultures are best incubated at 30°C.

The best known member of the group is No. 3679, much used in heat resistance studies in inoculated packs of certain foods. Merrill and Reed ^{45a} observed that it grew better, i.e., gave higher counts when grown in pork agar medium in deep "shake" tubes. The same experience held for *Clostridium botulinum*. Definitely higher counts were also secured when both putrefactive anaerobe No. 3679 and *Clostridium botulinum* (strain 62-A) were incubated at 27°C. instead of 37°C. The incubation time which Merrill and Reed used was 21 days. They also reported higher heat resistance of strain 3679 when the pork agar medium was used.

It was also reported ^{45a} that this organism is somewhat inhibited by salt in concentrations of 2.5 per cent and completely so by 7.5 per cent.

2. *Clostridium thermosaccharolyticum*, strain No. 3814. This is a thermophilic anaerobe which is used for semi-acid products where approximate end point of survival is to be indicated by spoilage.

3. *Bacillus stearothermophilus*, strain No. 1518. This is a flat-sour-producing organism and is used in foods in which flat-sour spoilage is the problem. Spores of this organism are much more resistant to heat than spores of the putrefactive anaerobic types. Thus where the maximum resistance of *Cl. botulinum* in phosphate buffer solution at 115°C. (239°F.) is 10 minutes, and of No. 3679 is in the range of 15 to 16 minutes, the resistance of the thermophilic anaerobe No. 3814 is in the range of 60 to 70 minutes and of flat sour No. 1518 is 130 to 140 minutes.

Williams said that the choice of which organism to use in a product is governed by the nature of the product and, to some extent, by the objective of the work. If a process protective against spoilage owing to thermophilic bacteria is desired, the flat-sour type is the organism of choice for low-acid products. With products in which thermophilic spoilage is not a problem, or where a process protective of health but not necessarily protective against thermophilic spoilage is desired the putrefactive anaerobe is the organism of choice. This latter type gives irregular growth in semi-acid products, but this fact does not speak against its use. With such products all inoculated cans are subcultured, and the determination of the end point is based upon the cultural results rather than upon the spoilage results.

An equally difficult question is the number of spores which shall be used. The National Cannery Association believed that this should not be fixed but should be graded to obtain definite resistance values. In work of this kind one never knows what natural contamination would be.

The process range should start with one which will result in 100-per cent spoilage on one extreme and include, on the other, one which will result in no spoilage. Possible processes between these points will have to be evaluated on their merits, if that which gives complete sterilization cannot be used.

^{45a}. Merrill and Reed. 1940. Nat. Cannery Assoc., Ann. Rpt. to Res. Committee, p. 16.

Fractionation of Spore Suspensions. When using inoculated packs to secure information on process times and temperatures it becomes necessary to obtain spore suspensions of heat resistant bacteria with which to inoculate the food under study. If the object is to destroy *Clostridium botulinum*, it is desirable to have an organism with a resistance in phosphate buffer solution pH 7.0 of from 10 to 15 minutes at 115.5°C. (240°F.); if on the other hand, the object is to guard against spoilage, a more resistant organism must be used which will resist heating for 35 minutes at 240°F. Owing to the fact that wide variations may exist in the resistance of spore suspensions prepared from the same strain of a bacterium, Yesair and Cameron^{45b} sought a method of bringing some order into spore inoculation work. They did it by "fractionating" spore suspensions into fractions with different heat resistances by use of a supercentrifuge. The medium in which the spores (putrefactive anaerobe) had been propagated was centrifuged. The effluent was recentrifuged and this was repeated several times. Thus three spore suspensions were secured which had the following heat resistances:

1st Fraction: survived 20 min. at 240°F., destroyed in 25 min.

2nd Fraction: survived 10 min. at 240°F., destroyed in 15 min.

3rd Fraction: survived 5 min. at 240°F., destroyed in 10 min.

This makes it possible to obtain spores of any desired resistance up to the maximum resistance of the spore suspension. If a spore suspension with a resistance of 30 minutes at 240°F. is desired, it is only necessary to obtain a spore crop with higher resistance and apply the centrifuge method to obtain spores of lower resistance.

Calculation of the Theoretical Process. Ball²⁹ briefed this procedure as follows:

1. Determination, by the glass-tube method, of the thermal destruction times at different temperatures of the organism which is known or assumed to be present in the food. In these tests, the organisms are suspended in a medium as nearly like that provided by the food itself in the can as it is possible to use. The data are plotted in a curve known as a thermal death-time curve, the two coordinates of which express time and temperature, respectively.

2. The rate of heat penetration to and the rate of cooling at the centers of the cans of food, identical with those for which the process is to be determined, are found by making tests with instruments specially designed to measure temperature at the center of a can. A thermocouple and potentiometer indicator are generally used for this work. These data are plotted in time-temperature curves known as heating and cooling curves.

3. The data represented by the heating, the cooling, and the thermal death-time curves are treated mathematically by the methods described in N.R.C. Bulletin No. 37.²⁸ The result gives the time theoretically necessary to process the cans at the given temperature to give complete sterilization with respect to the organisms studied in heat-resistance tests.

The best method of checking the validity of calculated processes is to run heat-resistance tests by the can method. This method consists of actually processing cans of food that have been inoculated with the organism on which the glass-tube heat-resistance tests had been made. Checks made in this manner have demonstrated that the

45b. Yesair and Cameron. 1936. Nat. Canners Assoc. Ann. Rpt. to Res. Committee for 1935, p. 11; also for 1936, p. 11; J. Bact. 31 (1936), 2-3.

degree of dependence that may be placed in calculated processes is directly proportional to the degree of accuracy with which the conditions can be controlled.

The National Canners Association³⁰ has published recommended processes for nonacid foods. Processing such foods in boiling water was not recommended.

Commercial Sterility of Canned Foods. The ideal process would probably be one which would destroy all forms of life in the can of food. This would be a condition of "absolute sterility" such as is thought of in surgery. While this would be possible to attain in canned foods by using sufficiently high temperatures for sufficiently long times, the food would probably be ruined as a commercial article. Consequently, canning technologists and others have come to recognize a condition of relative sterility for canned foods known as "commercial sterility." A "commercially sterile" canned food is one which has been processed by heat in such a manner that it will not spoil under ordinary market conditions, even though it may not have been completely sterilized. The few organisms which survive are usually sporeforming bacteria of no sanitary significance or hazard to human health. These are often thermophilic bacteria in the spore stage which cannot germinate if the food is held at temperatures below 43.3°C. (110°F.). Occasionally spores of anaerobic mesophilic bacteria may survive.

The only organism which worries the canner is *Clostridium botulinum*. Attempt is made, when processes are being determined, to destroy the most resistant spores of this organism.

Acidification of Canned Foods. As discussed more completely elsewhere in this chapter, canned foods are roughly grouped into two classes, acid foods and nonacid foods. The former are generally satisfactorily processed at 100°C. while the latter must be given a steam-pressure cook at temperatures above boiling. Among foods in the latter group are a number (brussels sprouts, artichokes, broccoli, and mushrooms) which are ruined for the market by such heavy processing. In order to be able to give them lighter processes, they are acidified to lower the pH below 4.5, which is recognized as critical for development of *Clostridium botulinum*. It should be clearly recognized that the spores of this organism may not be destroyed but are merely prevented from developing. Consequently, it is most important to insure that the pH is below 4.5. Cruess, Fong, and Lin⁴⁸ published the results of a study of this question. The importance of pH in processing was also brought out by Bigelow and Esty,⁴⁹ Bigelow⁵⁰ and Ball.²⁸ Bigelow showed the logarithmic nature of thermal death-time curves.

Food-Phosphate Factors. These were introduced to provide a means of expressing heat resistance of an organism when both neutral phosphate and the food under consideration are taken into account.

48. Cruess, Fong, and Lin. 1925. Hilgardia (Calif. Agr. Expt. Sta.) 1, 507-508.

49. Bigelow and Esty. 1920. J. Infect. Dis. 27, 602-612.

50. Bigelow. 1921. Idem 29, 528.

They are arrived at as follows:

$$\frac{\text{thermal death time in food juice}}{\text{thermal death time in phosphate (pH 6.98)}} \times 360.$$

The decimal thus secured is known as the "food factor." The two tests are made simultaneously. The value 360 in this equation is the thermal death time of 212°F. of the most resistant strain of *Clostridium botulinum* which has been isolated. The food factor is, therefore, a ratio of the resistance of the organism under study to its resistance in neutral phosphate solution.

Criticisms of "food factors" are the same as those for thermal death-time determination. Furthermore, the actual food itself is not used and the conditions under which it is canned are not maintained. Penetration of heat into a food juice would probably take place at a quite different rate than in the food itself. Other possibilities for variation, if not error, may be mentioned.

COOLING OF CANNED FOODS

After processing, the canner must lower the temperature of the can as rapidly as possible and as low as possible. The heat must be removed in order to stop the cook. Unless this is done promptly, the canner may suffer losses owing to alteration of the color and other undesirable changes in the food.

The technical phases of cooling will not be discussed here. They are just about as complicated as are those involved in heating the can. This phase of the subject may be studied in the publications of Ball.^{28, 29} An article in the *Canning Age*, June 1924, stated that among the dangers to be avoided by proper cooling the following are important:

Thermophilic Spoilage. This may occur in pork and beans and in corn in which the process has not been quite sufficient to kill all the spores of thermophilic bacteria. If the cans remain hot at a temperature above 43.3°C. (110°F.) for a long period, spoilage is almost certain to result sooner or later.

Loss of Quality. The product which otherwise may have possessed good quality may suffer loss of quality owing to improper cooling, such as:

- (a) Stack burn, resulting in a darkened product occurring in corn, pork and beans, catsup, etc.
- (b) Cloudy liquor, occurring in peas.
- (c) Pink discoloration, occurring in the light-colored fruits such as apples, pears, etc.
- (d) Soft, mushy products, where the raw product is very tender and must be handled with care. In this group may be mentioned as examples, tomatoes, cherries, berries, dill pickles, etc.

The thermophilic bacteria which have been shown by various investigators to be widespread in nature, are especially significant in connection with cooling. They possess a high optimum temperature and therefore have a high maximum temperature. The spores of some strains are able to withstand the processes given some foods. When they do survive, the food which contains them must be adequately and promptly cooled and stored at a sufficiently low temperature to prevent germination. When the canned foods are adequately cooled and are stored in cool warehouses, they will remain satisfactory for a long time. Should the temperature

rise, owing either to warm weather or other factors, the spores germinate and spoilage results.

The canner may use one of a number of methods to get the heat out of the can. The following methods are used for water cooling:

1. The cans are dumped on a belt and sprayed.
2. The cans are dumped on a belt and dragged through a tank of cold water.
3. The cans may be passed through a tank of water in the crates used in the cooker.
4. The cans may be sprayed in the crates which are kept stationary.
5. The cans may be cooled under pressure.

Early canning practice involved only air cooling. This, at best, could only be a slow and perhaps inefficient method. The water cooling methods where the can is agitated a little probably get the heat out of the can most quickly.

Especially interesting are the mechanical coolers used frequently in connection with mechanical cookers. These are usually pressure coolers. The cooler is kept from one-half to two-thirds full of water and pressure is maintained with air to prevent distortion of the cans. The cans are delivered automatically to the cooler on runways from the cooker.

While, generally speaking, it is good practice to cool canned foods immediately after processing before they are stored in the warehouse, some canners secure good results by storing them away hot, without cooling. Cooking then goes on for an indeterminate time. Canners who do this make allowance in selecting process times for the cooking which may go on in the warehouse. Cans which are stored before they are cool may take a long time to come down to room temperature and may, therefore, remain for a long time at temperatures which are optimum for organisms which have survived the process.

Cooling water must be kept bacteriologically clean. It must not contain large numbers of bacteria which spoil canned foods. The vacuum of cans which are being cooled is increasing; if there are cans which are not tightly closed, some of these organisms may be drawn in and spoil the food during storage. Examination of the cooling water is one important part of studies on canning factory sanitation.

Attempts have been made in recent years to sterilize water in the cooling tank with chlorine. This practice rests on results of experiments which have shown its value. Scott,⁵¹ Cameron,⁵² Woerz,⁵³ and Merrill⁵⁴ have reported their observations which clearly demonstrated reduction of spoilage bacteria. About two p.p.m. has been found to be sufficient to keep the water free from living bacteria. Scott reported that some of the cans were rusted but Woerz never encountered them.

The Container (Tin Can). While glass jars are used to some extent for preservation of foods in hermetically sealed containers, tin cans are much more widely used. The number of sizes and shapes is very confusing. According to Bitting, many factors have been responsible for present sizes.

54. Merrill. 1938. *The Canner* 86, No. 12, Pt. 2, 67.

First, cans were made to utilize a standard sheet of metal; later, they were made to hold a definite amount of food, either by volume or weight. Finally, cans were made to hold a quantity of a product to retail at a certain price. Cans are made from tin plate, which is sheet steel rolled very thin and coated with tin.

Manufacturers of tin plate have carried out much research to perfect their product. Some of these investigations, especially those⁵⁵ to determine how various tin plates behave when used for making cans in which various products will be preserved, have cost large sums of money. The layman is prone to lay many of the supposed defects and difficulties in preserving canned foods to tin plate with a thin layer of tin. He fails to realize that, at best, plate is not completely covered with tin. The weight of tin on the plate may be said to have little significance in food preservation.

When canning started in this country as a method of food preservation, the cans were put together with solder. These handmade cans were soon followed by those made with machines, and solder was still used. Later still the "hole and cap" can was developed and widely used until it was replaced by the modern "open-top" or sanitary can. The "hole and cap" can had a hole in the cover through which the food was introduced. A solder-hemmed cap was then placed over this hole and heat applied to close the can. Objections on the part of the consumers and practical disadvantages made a place for the "open-top" can of today. It is easier to clean and more easily filled. It does not necessitate reducing foods to a pulp. The only solder used on a "sanitary" can is at the side seam and this is so small in amount that it cannot possibly affect the contents if one is prone to consider its use objectionable. The double seam must be carefully and accurately executed, else the can will not be sealed tightly. The components of the double seam are shaped like the letter "U." The leg of one letter (the top) is placed between the legs of the other (the can). When these are firmly pressed together, a joint is secured which is called a double seam. The parts of the closing machine which fasten the cover to the can are very important and are given constant attention throughout the canning season. These are spoken of as the chuck, first operation seaming roll, and second operation seaming roll. (See Fig. 4.) These are very carefully machined. The chuck, as is well indicated in the illustration, fits into the countersink of the can covers. This acts as a wall against which the seaming rolls act to make the double seam. The first seaming roll folds the flanges on both the can cover and the side of the can together. Both pieces of metal are given the "U" shape. The second operation seaming roll then presses these "U"-shaped pieces of metal together, which, with the gasket between, should make a tight joint. The operation of the rolls in perfecting a double seam is influenced by the can lift which lifts the can up to the rolls. If the can is not lifted high enough the flange on the

55. "Relative Value of Different Weights of Tin Coating on Canned Food Containers." Report of an investigation by a technical committee representing the National Cannery Association, the American Sheet and Tin Plate Company, and the American Can Company, National Cannery Assoc., Wash., 1917. Also "Canned Food Containers," Bull. 22-L., National Cannery Assoc., Washington, D. C., 1923.

sides of the can is too short or it may be made too long by lifting it too high. The double seams are usually made according to certain dimensions which need not be mentioned in a book of this nature. Detailed information, however, may be found in papers by Miller,⁵⁶ Foss,⁵⁷ and Stevens.⁵⁸

Some cans are enameled on the interior and are known as enamel-lined cans. The enamel may be applied either before the tin plate is cut, or it may be sprayed into the can after it has been made, or both. It is not used so much to prevent corrosion, although it may function in this way with one or two foods, but to cause the container and its contents to retain their natural color.⁵⁹ With products subject to perforations, enameled cans usually pin-hole faster than plain cans; for example, this is true with

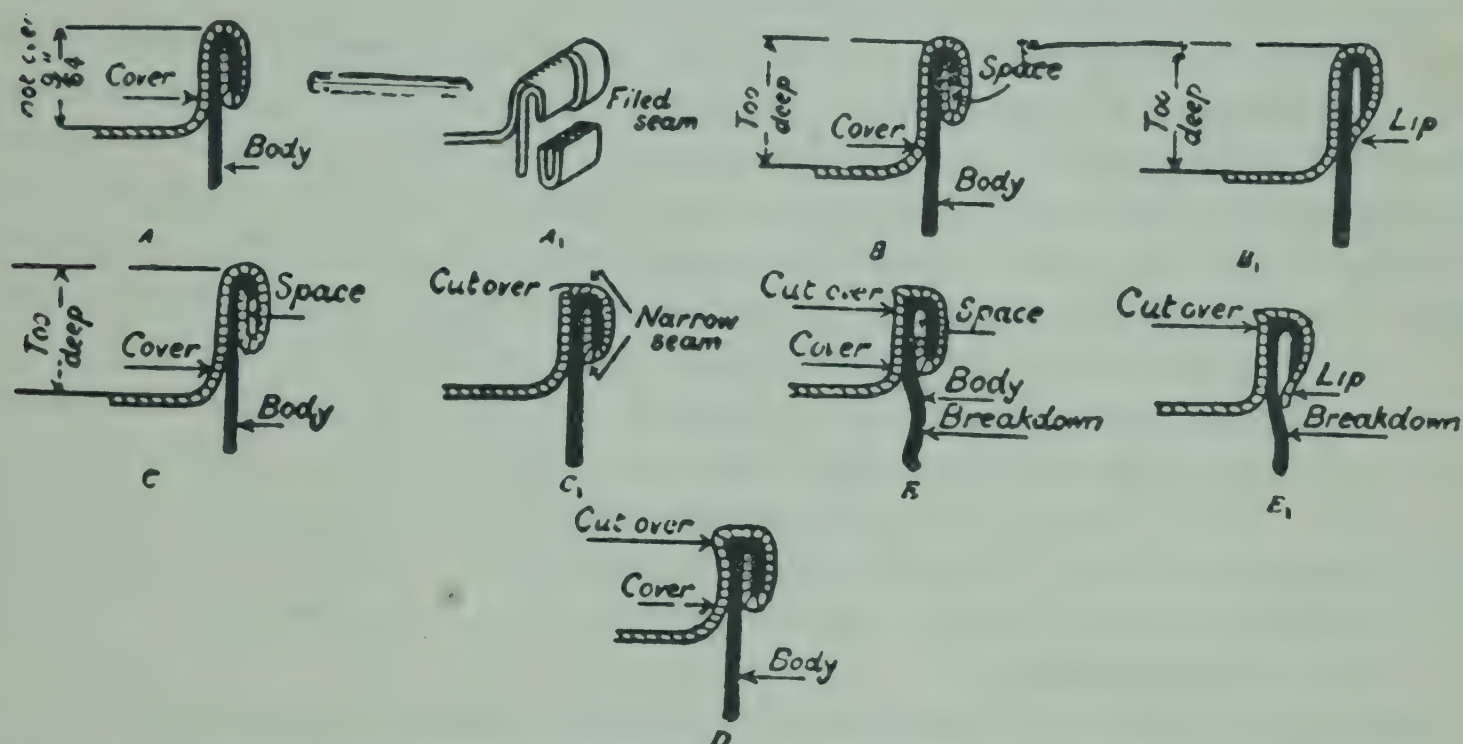

FIG. 4. Showing construction of double seams on sanitary cans. (After Esty and Stevenson, 1925.) A and A₁, correct completed seams; B and B₁, incorrect seams due to incorrect setting of seaming rolls on closing machine; C and C₁, incorrect seams due to incorrect setting of machine; D, incorrect seam resulting from worn seaming roll; E and E₁, incorrect seam due to too much base pressure.

apples and cider. Perforations are troublesome to canners of acid fruits. Elimination of air in such fruits has been found to reduce perforations to a minimum. In this manner the exhaust becomes a very important factor in canning procedure. The presence of air gently increases perforation.

Considerable investigational work has been done on the theory and chemical mechanism by which air is related to perforation. This will not be reviewed in this book. Those who desire to study this phase of the question may secure a start in the literature by consulting the publications of Kohman.

Corrosion of Tin Cans. This subject is not microbiological in nature and, consequently, must be but briefly treated here. Mantell and Lincoln⁶⁰

56. Miller. 1926. *Canning Age*, Aug., 1926.

57. Foss. 1923. *Canning Age*, April, 1923.

58. Stevens. 1927. *Canning Age*, Sept., 1927; July, 1928, p. 609.

59. This point is borne out by the use of plain cans for Royal-Ann cherries. Plain cans are used in this case to reduce the color in the red spots. The trade desires such cherries without color.

60. Mantell and Lincoln. 1926. *Canning Age*, Oct., 1926.

distinguished three types of corrosive effects: discoloration, perforation, and etching. Great emphasis has been placed on the relation of air to this problem. Huenink⁶¹ found it very important in canned apples, but not so much so in pumpkin. Clark⁶² continued Huenink's work by analyzing the gas. It was too rich in carbon dioxide and too poor in oxygen to be air. The subject has been developed much further by Kohman,⁶³ Culpepper and Magoon,⁶⁴ and many others.

Cleaning and Sterilization of Tin Cans. It is obvious that thorough washing of the tin can in which foods are to be preserved may be an important step in canning. Bitting⁶⁵ reported that sterilization of the container insured greater freedom from spoilage. Kremer and Klueter⁶⁶ of the Wisconsin Dairy and Food Commission, who made an extensive study of the sanitary condition of cans at the filling machines, believed that adequate washing was necessary. Fellers⁶⁷ examined 387 unused cans and jars for microorganisms. The counts ranged from a few hundred to 162,000 bacteria and 22,000 molds per can in one cannery. Cans received from the manufacturer contained fewer microorganisms. The principal groups of organisms found were cocci 28.1 per cent; aerobic, sporeforming bacilli 14.8 per cent; nonsporeforming bacilli 10.4 per cent; anaerobes 21 per cent; *Actinomyces* 6.7 per cent; molds 24 per cent; yeasts 5.6 per cent; and undetermined 8.3 per cent. Thermophilic bacteria were relatively abundant. In his extensive work on canned marine products Lang⁶⁸ also found the can to be a source of microorganisms. Among these was *Clostridium botulinum* Type A, which was found to be present in one per cent of 200 cans examined.

Storage of Canned Foods. Canned foods must be stored under good conditions. Temperature is very important from the microbiological as well as the chemical viewpoint. Chemical reactions between the container and its contents are materially retarded at low temperatures, and thermophilic bacteria are inhibited. Kohman and Sanborn⁶⁹ studied these problems. Sweating, leading to rusting and deterioration, may also occur if the cans are held at warehouse temperatures higher than the temperature of the cans themselves. Proper storage of canned foods may conserve quality as Joslyn⁷⁰ and Norris⁷¹ advised. Both advised holding at 0°C. (32°F.) in order to reduce chemical changes which lead to deterioration.

HOME-CANNED FOODS

Just how our modern methods of home canning originated is not known. They could not have been derived from the type of experiments which are known to be necessary today. The science of bacteriology had not yet come

into its own as an aid to canning technology. Among the first publications to disseminate instructions for home canning was Farmers' Bulletin 359⁷² issued in 1909 by the United States Department of Agriculture. In this a five-hour process in boiling water or intermittent sterilization was recommended even for nonacid foods.

In 1918 Benson⁷³ gave the next statement for the United States Department of Agriculture on home-canning technic. In this bulletin attention was called to the fact that hitherto the canning of vegetables and meats had been generally considered to be too complicated for the home, but that by the method adopted by the Department it was found to be relatively simple to can practically any food product in the home with ordinary kitchen equipment. This method of canning, described by Benson, was intended primarily for use in northern and western states. Why it could not apply equally well to foods packed in other sections of the country was not stated. Three general methods of processing were recommended: hot water-bath (212°F.), water-seal process (214°F.), and the steam-pressure cooker. Apparently, the boiling-water process at 212°F. was not giving satisfactory results. The instructions which were given for operating these outfits concerned mainly the mechanical features of the procedures. Practically no discussion of basic bacteriological problems was presented. A time table was included for processing all sorts of foods according to the several methods mentioned above.

Farmers' Bulletin 853 by Creswell and Powell⁷⁴ also appeared in 1918, recommending procedures for home canning of fruits and vegetables to canning club members of southern states. Considerable attention was given to sterilization and processing of home-canned foods and causes of spoilage. The homemaker was thus given the reasons for processing. A distinction was made between sterilization and processing. The former was applied to methods wherein all living microorganisms were killed and processing to a heat treatment which made the foods keep under proper conditions of storage even though viable spores might still be present. The new departure in this bulletin in methods of processing was introduction of "fractional" or intermittent sterilization in hot water and the pressure cooker. The intermittent method of processing was suggested because of the fact that spores of some species of bacteria resisted five hours' boiling. It was hoped that spores which survived the first heating period would germinate into vegetative cells and be destroyed during the second or third sterilization period. The authors stated that processing for one to one and one-half hours in boiling water on three successive days would ordinarily sterilize beans, peas, and corn in quart jars. During warm weather an interval of 18 hours between process periods was advised.

Farmers' Bulletin 1211, published in October 1921,⁷⁵ contained a much more complete discussion of processing, especially as far as different methods were concerned. Both the "one-period" or "continuous" process and

the "fractional" or "intermittent" process in boiling water were described. The time tables included suggested processes for boiling water and in the steam-pressure cooker.

Farmers' Bulletin 1471, by Stanley⁷⁶ appeared in May 1926. The suggested procedures in this bulletin show a distinct departure from those in the above-mentioned bulletins, and, for the first time, results of bacteriological research seem to have been considered. The process methods were arranged for acid and nonacid foods. Since it had been shown that *Clostridium botulinum* might survive six hours' boiling, the recommendations read that nonacid vegetables and meats should be processed under steam pressure. Boiling-water processes were permitted for fruits, tomatoes, pickled beets, and pimientos. The 1931 and 1932 revisions of Bulletin 1471 contained few modifications. An entirely new edition of this publication appeared as Farmers' Bulletin 1762, by Stanley, Steinbarger, and Shank in September 1936, followed by several revisions. It repeats instructions concerning canning given in Bulletin 1471 and recommends that nonacid foods should not be canned in the home if a pressure cooker is not available for sterilization.

The above discussion might suggest that the Bureau of Home Economics was the only bureau in the United States Department of Agriculture which has been concerned with canning technology. Such was not the case, for Magoon and Culpepper⁷⁷ of the Bureau of Plant Industry for some time prior to 1926 had been studying and publishing the results of experimental work on canning technology. While their work was not directly concerned with home-canning problems, their data showed convincingly the inadequacies of many procedures recommended. Thus there was involved the interesting situation of the Department's issuing through one of its agencies recommendations which were bacteriologically unsound, while from another bulletins were being published which gave bases for safe recommendations.

Practically all states have issued bulletins giving instructions for home canning. Examination of these publications indicates that the recommended procedures vary greatly. Some of them are acceptable from the point of view of good canning technology but most of them are not. Many such authorities are not following the recommendations of the United States Department of Agriculture as recorded in Bulletin 1762. They still recommend processing of nonacid foods in boiling water, thus making it possible for the foods to spoil or lead to intoxications.

Other sources of information for home canners are publications distributed by manufacturers of apparatus and supplies for home canners and by magazine and newspaper food bureaus. Many statements in these publications are both misleading and scientifically unsound. Moreover, their recommendations often show inconsistencies similar to those noted in some of the extension bulletins. Popular cookbooks are also inclined to

76. Stanley. 1926. U. S. Dept. Agr., Farmers' Bull. 1471.

77. In addition to these federal bulletins are many from state experiment stations, some are reliable but most of them are not.

fall into such errors and inconsistencies, and even home economics textbooks might well be examined on these points before their recommendations are accepted without qualification.

Methods of Processing Home-Canned Foods. The common methods of home canning are briefly discussed from the bacteriological point of view in the following paragraphs.

The Cold-Pack. This method involves packing raw materials into jars cold, followed by brining or siruping, closing, and heating usually in a water bath. It has been responsible for much spoilage and many outbreaks of botulism since its introduction about 1917. When used for preserving vegetables and meats, it is a dangerous method. When used on fruits it may give many jars which are not sterile; considerable spoilage will result unless they are stored under ideal conditions not always available in the ordinary home. This method permits practically the entire load of microorganisms on the raw materials to go into the jar, since blanching may not destroy many of them. The process to which the jars are subjected must then be relied upon to destroy spores. Results of many experiments have shown that hot-water-bath processing of cold-packed vegetables and meats does not sterilize them. The Bureau of Home Economics has characterized this method of processing as wasteful and dangerous.

The origin of the process times recommended for the boiling-water method is difficult to determine. They could not have been based on results of bacteriological examination of jars so canned nor an adequate examination, after incubation, of experimental packs. Had such data as well as those from heat-penetration studies been considered, the times indicated would have been far too long to command the attention of the home canner.

The Hot-Pack. The foods are precooked for a period of time before they are packed into the jar. The jars are processed immediately. Such treatment probably yields a safer food than the cold-pack method although there is no certainty that bacteria are destroyed in the kettle. However, if precooking in the kettle is sufficiently long and is done at sufficiently high temperatures, viable bacteria are probably materially reduced in numbers, thus leaving fewer to be destroyed when the jar is cooked.

Oven Processing. This method is recommended by stove manufacturers and some manufacturers of canning equipment to be used in the home. It is an expensive and unsafe method to use. Oven-processed foods in glass jars are unsealed during the processing, and therefore the temperature may not go above 212°F. Consequently, the temperature at the center of the jar of food never reaches oven temperature (250 to 275°F.). Heat penetration is slower with this method of processing than with any other. Studies at the Indiana Agricultural Experiment Station⁷⁸ have shown this. When processing a quart jar of water with an initial temperature of 68°F. (20°C.) in a preheated oven with heat regulator set for 275°F. (135°C.), from 95 to 110 minutes were required for the contents of the jar to reach boiling temperature; whereas for a similar jar at the same initial tempera-

78. Indiana Agr. Expt. Sta., Rpt. of Director for 1930, 51-52.

ture processed in a water bath of vigorously boiling water, only 20 to 25 minutes were required for the contents to reach the boiling point. With higher initial temperatures, the difference in time in the two methods of processing was not so great. When the initial temperature of the contents of the quart jar was 158°F.(70°C.), it required from 50 to 55 minutes for the temperature at the center of the jar to reach the boiling point when the processing was done in a preheated oven set for 275°F. and 15 to 18 minutes when the processing was done in the water bath.

Further information on this subject was published by Stienbarger.⁷⁹ In her experiments the oven temperatures, 250 and 275°F., generally recommended for oven canning were used. Quart glass jars were used in all tests. Temperatures were registered by thermometers from the centers of the jars. In the following temperatures, corrections have been made for the heat of the oven, which in these instances was 275°F. Cubed squash, with an initial temperature of 108°, reached 175°F. in 70 minutes and 212°F. in two hours. Crushed squash with a higher initial temperature, 147°F., required 95 minutes to reach 175°F., and two hours to reach the boiling temperature. Sliced carrots with initial temperatures of 140 to 147°F. reached 212°F. in 65 to 75 minutes. Green beans cut into one-inch lengths with initial temperatures of 180 to 183°F. reached 212°F. in 30 minutes and others with initial temperatures of 167 to 169°F. required 60 to 75 minutes to reach 212°F. Spinach, with an initial temperature of 171°F. reached 212°F. in 78 minutes, whereas another jar with an initial temperature of 165°F. reached 212°F. in 95 minutes. Plums with an initial temperature of 163°F. reached 213°F. in 55 minutes, but a similar jar with an initial temperature of 133°F. required 86 minutes to reach 213°F. Applesauce, with an initial temperature of 156°F., reached boiling in 60 minutes, while with an initial temperature of 86°F. another jar required 95 minutes to reach the boiling point.

In order to secure actual information on the behavior of *Clostridium botulinum* in oven-processed foods, experiments were carried out during the winter and spring of 1931 in the author's laboratory. The vegetables were packed in glass jars in the usual manner. After inoculation the jars were then placed in an oven regulated to 135°C.(275°F.), when the timing was begun, and processed for five hours. A jar was removed from the oven every 15 minutes after the first hour and a half. As soon as the jar has been removed from the oven, the seal was completed at once and the jar air-cooled by an electric fan. The jars were inverted, allowed to stand overnight, and examined the next morning for imperfect seals, after which they were incubated at 37°C. for from one to five days. When the jars were removed from the incubator they were dipped into lysol solution and dried before opening. Samples were removed with sterile glass tubing. A sample was removed for feeding directly to guinea pigs and another for culture. There is little need for discussing the results in great detail. They showed that even a five-hour process in an oven at 135°C.(275°F.) did not destroy spores of *Clostridium botulinum* in the foods used.

79. Stienbarger. 1931. U. S. Dept. Agr., Yearbook, 418-419.

The temperature in the jar located in a hot-air oven should not rise perceptibly above 212°F., as the container is only loosely closed, and loss of the product will occur if heated above 212°F. The curves indicate that jars placed in an oven really heat more slowly, and do not obtain a temperature during the process above that reached in the boiling-water bath.

The pressure process suggested for products such as peas should produce adequate sterilization; however, the boiling-water processes of 180 minutes or oven processes of 180 to 240 minutes suggested by some of the prominent home-canning books will obtain only from 10 to 16 per cent of the sterilizing value of suitable pressure processes.

Hot Water-Bath Processing. This method of processing was probably introduced into home canning from the bacteriological laboratory where it was used for sterilizing materials which were believed to be decomposed by steam-pressure sterilization. Such materials usually have a light load of bacteria and if properly handled may be sterilized by heating at 100°C. (212°F.) for varying lengths of time. The situation is quite different for vegetables in glass jars. Here the bacterial load is usually quite heavy and, in turn, may include decidedly heat-resistant species.

The sterilizing value of this, as of any process, depends largely on the penetration of heat into the container. Less work has been reported on heat-penetration rates into jars used in home canning than into tin containers used in the factory. Those who desire information on the rate of heat penetration into foods in glass jars may consult the publications of Magoon and Culpepper.²⁷ One of the first to give attention to this subject for home-canned foods was Denton.⁸⁰ She reported that it required 45 minutes for the temperature at the center of a jar of sliced carrots to reach 98°C., where it remained during the rest of the processing period. This meant that the internal temperature was at its maximum (98°C.) for 75 minutes. Castle⁸¹ also used a thermometer fitted into a hole in the tops of Mason jars which were processed in boiling water. The important finding from her paper for this discussion is the long time required for the interior of the jars to come to 100°C. In most cases this greatly exceeded the process times recommended in bulletins on home canning. In the last conclusion drawn from her paper Castle warned that vegetables preserved in this manner should always be heated before use to avoid danger of botulism. Heat-penetration studies in an extensive investigation on home canning at Iowa State College by Redfield, Nelson, and Sunderlin⁸² also showed slow penetration of heat into glass jars.

Glass jars are usually left only partially sealed when processed in boiling water. In Massachusetts recommendations were that the jars should be fully sealed. In order to ascertain whether this method was safe and satisfactory, Fellers, Levine, and Maclinn⁸³ observed some 16,500 jars of many different products packed in western Massachusetts. Partially sealed jars developed only negligible pressures while those which were fully sealed

developed from two to six pounds' pressure which was withstood without bursting. This was believed to be practical in every way.

The Steam-Pressure Cooker. This is by far the safest method of processing, but the recommendations in many bulletins are somewhat indefinite. Steam pressure of only 10 pounds is recommended by one large jar manufacturer for all goods. Another with essentially the same process times recommends steam pressure of from 10 to 15 pounds. Significance of the relation of temperature to pressure is subordinated. Practically all "authorities" on home canning advise the homemaker to follow the directions which come with the cooker.

The steam-pressure process has been recommended by the Bureau of Home Economics of the United States Department of Agriculture. Containers of nonacid vegetables processed according to the recommendations of the Bureau gave only two per cent of spoilage. If a pressure cooker is not available, some method of preservation other than canning should be used for vegetables. Botulism outbreaks argue against the boiling-water process.

The success of any method of processing canned foods is determined largely by the rapidity of heat penetration into the container and the thermal destruction time of spoilage microorganisms at the pressure and temperature. This is easily understood when thermal resistance of *Clostridium botulinum* at 212 and 240°F. is compared. The resistance of this organism at 212°F. is 330 minutes while at 240°F. it is only 10 minutes in neutral phosphate solution. Unless sufficient heat penetrates to the center of the jar to destroy microorganisms the product may spoil. Much sound information is available from careful studies long since reported by Ball,²⁹ Magoon and Culpepper,²⁷ and Bigelow, Bohart, Richardson, and Ball.²⁶ These publications cover the subject quite completely and present sufficient data for those advising home canners, if they will only use them. Magoon and Culpepper studied the glass jar with various foods.

As the relation of inadequate processing to botulism and the relatively greater difficulty of processing nonacid foods was established, acidification of nonacid foods with lemon juice or vinegar was suggested. Having established that a pH of 4.5 had protective action by inhibiting development of *Clostridium botulinum*, it was believed that this could be attained by addition of acid. Nonacid foods are highly buffered; consequently such large amounts of acid would have to be added that flavor would be affected. Sunderlin, Nelson, and Levine,⁸⁴ for instance, found that acidification of asparagus and sweet corn with phosphoric or citric acid made a two-hour process satisfactory, whereas without acid even a process time of twice as long was not sufficient.

No outbreak of botulism has been caused by foods canned in American factories since 1924.* This fortunate situation results from careful studies about *Clostridium botulinum*, heat penetration into canned foods, and

84. Sunderlin, Nelson, and Levine. 1928. Iowa State Col. J. Sci. 2, 189-212.

* One outbreak was attributed to a mushroom sauce which may be considered to be a specialty product and not an ordinary canned vegetable packed in great amounts.

other factors important in canning. The situation for canning in the home is not so satisfactory. Each year sees its toll of human lives which, to a great extent, may be credited to some extension services, editors of cook-books, and manufacturers of supplies for the home canner. How long such a situation will be allowed to continue remains to be seen. In some states serious outbreaks of poisoning had to occur before any real advance could be made in changing unsound recommendations. Recent summaries of outbreaks and cases of botulism in California⁸⁵ by the California Department of Public Health for the years 1899-1939 indicated 130 outbreaks, 300 cases, and 184 deaths. Meyer and his associates in the same state gathered statistics of 367 outbreaks in the United States over the same period. Only 83 were caused by commercially canned foods. The other 284 outbreaks were caused by home-canned foods. Total cases in the 43 years numbered 1,052 with 687 deaths, a fatality rate of 65 per cent. How many unrecognized cases occurred will never be known.

If graduates of schools of home economics and others who consider themselves capable of recommending procedures for the homemaker do not recognize all bacteriological knowledge, they should be forced to do so by those whose duty it is to conserve the public health. (This has been done by the Food and Drug Administration.⁸⁶ Interstate shipments of foods processed in boiling water were seized and destroyed.) It would be unfortunate to have to resort to legal procedures to indicate that those who distribute unsound literature have some responsibility to the public. Furthermore, those who interpret scientific data for those who are less informed, must leave nothing unsaid. Improperly processed home-canned foods are hazardous.

Canned-food technologists are agreed that nonacid foods must be processed only under steam pressure. Steam-pressure cookers have been devised for this purpose, but the mere use of such a cooker is not sufficient, for it must be correctly used and the non-technical homemaker must be taught to appreciate the necessity of following instructions which come with the cooker. Some of these instruction books should be more carefully written.

Practically all pressure cookers depend on a pressure gauge alone for controlling temperature. This is probably satisfactory if the gauge is of high quality and all air is removed from the cooker. The pressure gauges furnished with some cookers are probably untrustworthy. However, good canning practice should provide for a reliable thermometer with which the actual temperature may be determined. This is necessary not only because the atmosphere in the cooker may contain considerable air, but because the gauges may become faulty by use year after year without inspection and adjustment.

Bacteriological Condition of Home-Canned Foods. Two main problems are involved in home canning of perishables, spoilage and food poisoning. They are closely interlinked, for some of the organisms which cause intoxi-

85. Calif. State Dept. Pub. Health, 36th Biennial Rpt. for 1938-1940, 24-26; Amer. Med. Assoc. J. 121 (1943), 1286.

86. U. S. Food and Drug Administration, Rpt. of Chief for the Year Ending June 30, 1931, 10-11.

cations are also spoilage organisms. They may bring about gross evidences of spoilage and in addition form a metabolic product which is poisonous. Spoilage in home-canned foods has received too little emphasis because most homemakers keep no records. Any pack of home-canned foods in which considerable spoilage occurs is potentially dangerous. The argument that poisonings have never resulted in the area or state does not have much weight since it is known that *Clostridium botulinum* is widespread in nature.

Some who are serving in an advisory capacity to home canners take comfort from the fact that foods in which *Clostridium botulinum* has developed usually show visual evidences of spoilage and would, therefore, be excluded from the diet. This may be true for certain foods, but it may not be true for all home-canned foods. Schoenholz, Esty, and Meyer⁸⁷ showed quite clearly that evidence of spoilage and toxin formation were quite irregular. Foods in which there were no evidences of spoilage have caused serious outbreaks of poisoning.

Results of the few investigations which have been carried out are in good agreement. They show that home-canned foods frequently contain viable organisms and show high incidence of understerilization. Lang⁸⁸ found a heterogeneous flora. The most frequent cause of spoilage was an organism, said to have been a butyric-acid organism, isolated from 185 jars, spores of which resisted 100°C. (212°F.) for six hours, as well as intermittent processing at 100°C. for one hour at intervals of 18 and 24 hours. The frequency of occurrence of bacterial spores in jars of good quality varied from 20 per cent for tomatoes to 80 per cent for spinach. Spores of the subtilis-mesentericus group were able to withstand 100°C. for from five and one-half to 10 hours. Biester *et al.*⁸⁹ reported 50 per cent spoilage in foods processed in boiling water. The jars were incubated at 37°C. (98.6°F.) before examination.

Bacteriological examination of a large number of cans of asparagus packed in 1918 by the division of home economics at the University of Kansas⁹⁰ revealed many jars with viable organisms, most of which were heat resistant. A later report in 1920 indicated that *Bacillus subtilis* and *Bacillus mesentericus* predominated in jars to which salt had been added. Presence of acid to the extent of .1 per cent caused rapid destruction of bacteria.

The Bureau of Home Economics of the U. S. Department of Agriculture observed spoilage in home-canned foods of packs for two years (Stienbarger⁹¹). Results were just about the same as reported by other investigators. Of 3,434 jars of various kinds of food, 48 per cent showed spoilage after processing in the open water bath. The foods in which greatest spoilage occurred were meats, fish, corn, lima beans, and peas. Hot packing gave less spoilage than cold packing. The conclusion to be

drawn from this report is that high temperatures are needed for preservation of nonacid foods. These are attained only with steam pressure.

Perhaps the most extensive investigation of home-canning methods was carried out at Iowa State College by Sunderlin, Nelson, and Levine,⁸⁴ who made observations on 2,732 jars of vegetables and meats processed in boiling water. The data which were published do not speak well for home-canning procedures. With corn, for instance, 15 per cent spoilage was secured with a four-hour process, the longest which was used. Similar data were secured with several other foods. The authors stated that the possibility of food poisoning was not investigated. The large percentage of spoilage and the still larger percentage of unsterile cans would indicate to anyone familiar with botulism that practically all of the cans prepared in these experiments were potentially dangerous. Such data give further proof of the danger of using hot-water processes for nonacid foods. Under the conditions of their experiments, two and one-half hours in boiling water were found to be satisfactory for beans and chard and three hours for beef and pork.

Modification of the recommendations from the United States Department of Agriculture for home-canning technic was markedly affected by the botulism situation in the United States soon after 1916. Dickson⁹² tested the efficiency of the then recommended procedures using peas, beans, and corn. Each jar was inoculated with spores of *Clostridium botulinum*. The jars were placed in boiling water and processed according to instructions. After three weeks all showed evidences of fermentation with gas formation and a strong butyric acid odor when opened. Administration of filtered juice to guinea pigs caused death. These results caused Dickson to state that the cold-pack method of canning vegetables was neither safe nor efficient if the raw materials happened to carry spores of *Clostridium botulinum*. The United States Department of Agriculture through bacteriologists in its Bureau of Chemistry and States Relation Service⁹³ denied Dickson's statements. In spite of the fact that outbreaks of botulism were being caused by home-canned foods, they stated that there was no danger that botulism would result from eating fruits and vegetables which had been canned by any of the recommended methods provided the methods had been carefully followed. They further argued (on the basis of statements in textbooks) that the spores of *Clostridium botulinum* were destroyed by heating for one hour at 79.4°C. (175°F.). Evidence indicating a much greater heat resistance had already been published. Burke⁹⁴ showed that spores of *Clostridium botulinum* were very resistant to heat. She reported that the spores of some strains would resist boiling for three hours or more and that methods of canning by boiling the fruit or vegetables in an open kettle and sealing in clean jars by the cold-pack (one-period) method, or by fractional sterilization on three successive days, could not be relied upon to destroy the spores of *Clostridium botulinum*.

92. Dickson. 1917. Amer. Med. Assoc. J. 69, 966-968.

93. U. S. Dept. Agr. 1917. Weekly News Letter 5, 6.

94. Burke. 1919. Amer. Med. Assoc. J. 72, 88-92.

She stated that pressure canning with a sufficiently long sterilization period was the only safe method.

Dickson⁹⁵ in another statement emphasized again that prevention of botulism depended not on curtailing the use of either home-canned or commercially canned foods but upon education of the public to possible danger of botulism from improperly canned foods. Commercial canners faced this situation squarely and spent hundreds of thousands of dollars to learn proper methods of processing. The result is that commercially canned foods in America have been free from botulism hazards for about two decades.

Home-canning experts in many states take confidence from the fact that no botulism has been caused by products packed in their states. There is false security in such a position, for if the results of bacteriological research are to be believed, spores of *Clostridium botulinum* are widely disseminated in soil, and home canners constantly face the possibility of the presence of spores of this organism in home-canned foods. However slight the possibility may be, any illness with 60 per cent mortality is serious and naturally strikes terror to a community. When it is remembered that it can be prevented by proper methods of processing, carelessness becomes doubly inexcusable. Those who hold positions from which they may speak with authority on canning methods, must consider all phases of the problem and data which are being published every day. There is little reason for them to suggest dangerous procedures.

A few bacteriologists as well as a few teachers of home economics apparently believe that the possible relation of improperly home-canned foods to botulism is a much-flouted problem of little real significance. As has been pointed out, since 1924 there has not been a single outbreak of botulism from ordinary factory-canned foods; one outbreak has been attributed to a specialty, mushroom sauce. Bacteriologists, physicians, and health officers may have a part in correcting the present unfortunate situation. The time has come for a thorough appraisal of the procedures which are recommended to the homemaker for canning fruits, vegetables, and meats. Until recommendations such as are now distributed by the United States Department of Agriculture in Farmers' Bulletin 1762 are adopted generally, intoxication from and gross spoilage in packs of home-canned foods will continue. The yearly toll of deaths from botulism caused by home-canned vegetables and vegetable mixtures should stimulate health authorities to exert pressure which will lead to safe and adequate recommendations. Until these recommendations can be corrected spoilage and poisonings will continue. A warning has been issued by the California Department of Public Health.⁹⁶ Fellers⁹⁷ made an emphatic statement on this question and advised that something be done to curb the publication and distribution of dangerous literature. He called attention to the fact that the United States Department of Agriculture gives sound advise.

Schoenholz, Esty, and Meyer⁹⁸ as long ago as 1923 warned that foods canned in the home by some methods were unsafe. They stated that facilities for maintaining temperatures above the boiling point were not always available in the home. Furthermore, glass jars were usually used in which it would be more difficult to determine evidences of spoilage. Despite these warnings, every year since 1923 has had its outbreaks of botulism caused by home-canned foods. In addition to the above warnings are those of the American Public Health Association⁹⁹ and the American Medical Association.¹⁰⁰ Tanner¹⁰¹ reviewed the whole situation, pointing out that the responsibility of those who give instructions in home-canning methods is to give only methods which will insure a safe product that will keep.

Canning Compounds. To prevent spoilage and food poisoning resulting from faulty processing some home canners have resorted to use of chemical preservatives, such as salicylic acid, boric acid, and similar compounds. So-called "canning compounds" have been marketed. Levine¹⁰² examined one which contained 95 per cent of boric acid and five per cent of sodium chloride. The manufacturers recommended 15 to 20 minutes' boiling with seven grams of the compound per quart for the preservation of fruits and vegetables. In this concentration, Levine and Weldin observed a selective action on bacteria. Some varieties of *Escherichia coli* and several of the aerobic sporeformers failed to grow in media containing the compound. *Clostridium botulinum* grew in twice the concentration recommended. The compound seemed to have little effect on the bacteria usually present on vegetables. The same compound was studied by Edmondson, Thom, and Giltner¹⁰³ who arrived at similar conclusions. Boric acid at best is a feeble antiseptic. As a chemical preservative its use in foods is prohibited by the Food and Drug Administration.

MICROORGANISMS IN CANNED FOODS

While canned foods may not be completely sterile, they are in much better condition bacteriologically than in former years. Since some canned foods may contain viable microorganisms which do not develop as long as cans are held under certain conditions, they are characterized by canned food technologists as "commercially sterile." Investigational work in this field must be carried on under rigorous laboratory conditions to prevent contamination of plates and cultures. Air-borne contamination has been shown to occur. When testing sterility of a product such contamination becomes very significant. It would probably not be significant in such bacteriological work as water or milk analysis because a few more colonies would not materially affect the results. Williams and Clark¹⁰⁴ discussed

this problem for canned salmon. Their statements are probably applicable to other foods. Improvement in bacteriological condition of canned foods is also due to rigorous processes which have been introduced as well as to better technology in general.

A few of the earlier contributions are reviewed below because of their significance in the historical background of an industry which has been placed on a firm basis by science and technology.

Russell¹⁰⁵ isolated two different species of bacteria from canned peas which caused a gaseous fermentation. The organisms were probably facultative thermophiles, although it was not definitely established. The trouble was checked by raising the process. Poincarré and Macé¹⁰⁶ reported the isolation of living bacteria from several different kinds of canned foods.

About this same time canned sea foods began to receive the attention of bacteriologists. MacPhail,¹⁰⁷ in a study of blackening of lobster, isolated three bacteria and a micrococcus which were believed to be the causes of the trouble. The same year, Prescott and Underwood²⁴ isolated and described seven bacilli and two micrococci from canned clams and canned lobster. The next year, Prescott and Underwood spent the summer in Maine on a study of sweet-corn spoilage. Eleven bacilli and one micrococcus were isolated from spoiled cans. They were not cognizant, at this early day, of the importance of thermophilic bacteria but did report that there were two kinds of souring, one with gas formation and the other without. It is quite possible that the bacteria which were isolated were facultative thermophiles and grew on plates incubated at 37°C.(98.6°F.) or lower. They fulfilled Koch's postulates. Large losses were also being experienced in canning of peas. Harding and Nicholson¹⁰⁸ had an opportunity to study a serious outbreak of spoilage in central New York. The peas had a disagreeable odor resembling hydrogen sulfide. Whether this was the sulfide spoilage of peas of the present day probably cannot be known. Microscope examination of the liquor from a spoiled can revealed the presence of a rod-shaped, sporeforming organism. Experiments were conducted which showed that heating a two-pound can of peas for 30 minutes at 115.4°C.(240°F.) destroyed the organism. When this process was used in the factory, the spoilage ceased. Harding and Nicholson thus worked with a spoilage of peas which has more recently been found to be caused by thermophilic bacteria.

As early as 1904, von Wahl¹⁰⁹ discussed differences in the resistance of spores. He noted the fact that heat resistance is closely bound with the medium in which the spores are heated and that repeated cooking may so alter the menstruum that the heat resistance is changed. Other contribu-

tions were made by Belser,²⁵ Cathcart,¹¹⁰ Pfuhl,¹¹¹ McBryde,¹¹² Burgess,¹¹³ and Zavella.¹¹⁴

One of the most significant contributions to knowledge of spoilage of peas, corn, and many other canned foods was made by Barlow.¹¹⁵ He showed for the first time that thermophilic bacteria caused spoilage of canned foods. In order to determine the organisms which were causing the spoilage, he first worked with underprocessed corn. He also noticed that cans at the center of the stack in the warehouse showed greater spoilage.

Examinations of canned foods up to this time had been made largely on small numbers of cans and on cans which were spoiled. No large-scale examination of cans purchased on the market had been made. Consequently, publications of Weinzirl¹¹⁶ and Cheyney¹¹⁷ are especially interesting. They purchased cans of food on the open market which were apparently in satisfactory condition. While it is wrong to reach conclusions by summarizing data from fruit, vegetable, and meat products, Weinzirl reported that 19.2 per cent of sound cans of food contained viable spores. Many of the organisms isolated showed very low heat resistance which would seem to indicate that the cans from which they were isolated may not have possessed tight closure. Among the various microorganisms which were isolated were four thermophilic bacteria to which new names were given: *Bacillus aerothermophilus*, *Bacillus thermoidifferens*, *Bacillus stearophilus*, and *Bacillus thermoalimentophilus*. Cheyney found that only eight per cent of 725 cans contained viable organisms. In a private communication he reported that examination of 2,200 cans showed the same results. Savage¹¹⁸ also examined canned foods selected from importations into England. He examined 178 cans, excluding canned condensed milk which is known to contain viable bacteria, 38.8 per cent of which were not sterile. The percentage not sterile varied from 100 for crab, 83 for lobster, 64 for meat (kind not stated) to 22 for fruit (kind not stated). Savage considered the types of bacteria present to be more important than the sterility. Proteolytic and fermentative properties were the most important characteristics causing unsoundness. Savage punctured 17 sound cans of fish products to allow the ingress of sterile air. They were incubated for from five to 16 days and then sealed and incubated. Twelve of them spoiled. Savage thus showed that many cans of food contain viable aerobic and anaerobic bacteria which are stimulated to grow by the presence of air. The same thing was shown for yeasts in condensed milk. Viable yeast cells could be present in cans of condensed milk and cause no fermentative changes as long as air was kept out. Savage isolated a new

organism, *Bacillus pleofructi*, which was able to decompose canned fruit. Thus air ingress is regarded as of great importance, since it may allow the development of bacteria which are already in the can of food.

Twenty-four per cent of 900 cans of commercially sound canned corn was found by Michael and Tanner¹¹⁹ to have viable organisms. While these cans showed evidences of spoilage after they had been incubated, it is probable that they would have remained normal on the market. Imported canned shallots (onions) were found by Prickett¹²⁰ to harbor viable thermophilic bacteria. Anaerobic thermophilic bacteria were not found.

McClung and Wheaton¹²¹ found *Clostridium welchii* the cause of gas formation in boiled beef. The spoilage was peculiar because the cans were "swells" when they came from the retort, quite an unusual situation. The gas which caused the swelled condition was largely hydrogen. Failure to isolate viable bacteria from the cans greatly complicated the problem. Bacteriological surveys of the packing plant and raw products gave cultures in which a wide variety of bacteria were present. The specific organism involved was found to be *Clostridium welchii*. It seemed to the authors that the meat was contaminated with the organisms when received at the canning plant. During parboiling, the temperature was not raised sufficiently to destroy them. They quickly developed in the can of meat which was closed under vacuum. At this time the temperature of the meat in the cans was about 100 to 110°C. (212 to 230°F.) Delays in processing would give organisms sufficient time to develop. The presence of this organism was not believed to have any public-health significance.

SPOILAGE OF CANNED FOODS

Canned foods are subject to various kinds of spoilage. They may be attacked by microorganisms which have survived processing or gained access to the can through imperfections in the container or may undergo chemical spoilage by reacting with the metal of the container. The discussions in this book will consider especially spoilage caused by microorganisms. This is a broad, intricate subject in itself on account of the various types of food involved and the various types of microorganisms concerned in spoilage thereof.

Bacteria which spoil canned foods may be classified according to the changes which they produce or their own characteristics. These groups seem to be quite well demarked and are generally used for convenience, as pointed out by Cameron and Esty¹²² and Cameron, Williams, and Thompson.¹²³ Three groups are made up of thermophilic bacteria.

1. "*Flat-Sour*"-Producing Thermophilic Bacteria. These bacteria produce acid in cans without gas formation. Consequently the ends of the cans remain flat. Two types are involved depending on whether nonacid or acid foods are involved.

Preparation of Coenzyme Standard: Coenzyme I, suitable for establishing V-factor curves, was prepared from yeast by the method of Williamson and Green.²³⁷ A solution containing 1.5 mg. per ml. of a preparation of coenzyme previously dried to constant weight was passed through a Berkefeld filter. An aliquot of the sterile filtrate was compared with another sample of coenzyme I of which the purity had been established by analysis for phosphorus and by measurement of extinction coefficient at 3400 Å following reduction of dithionite. The filtrate was then diluted to contain 15 µg. of coenzyme per ml. delivered aseptically in 0.5-ml. quantities into sterile tubes, frozen and dried *in vacuo*, and stored in a desiccator over calcium chloride at 0°C. (32°F.). Frequent assays demonstrated that coenzyme preparations treated and stored in this manner are stable for many months. Klein²³⁸ described another procedure for the preparation of the pyridine nucleotides and their separation.

Determination of Nitrite Produced by Hemophilus influenzae: For the determination of nitrite the technic of Shinn²³⁶ has been found very satisfactory. In this method the color produced by the diazotization of sulfanilamide and subsequent coupling of the diazotized compound to N(1-naphthyl) ethylenediamine is a measure of the nitrite in the reaction mixture. From a 1-ml. pipette 0.1 ml. of the culture was delivered into a colorimeter tube containing 8.5 ml. of water. The interior of the pipette was then washed two or three times with a small quantity of the material in the tube to insure complete delivery. This was followed successively by 1 ml. of .2-per cent sulfanilamide, 0.2 ml. of 0.1-per cent N(1-naphthyl)ethylenediamine dihydrochloride, and 0.2 ml. of 6 N hydrochloric acid. The deep red color which developed upon coupling of diazosulfanilamide with N(1-naphthyl)ethylenediamine was maximum within 15 to 20 minutes and was stable for at least 24 hours. The color intensity was read in a photoelectric colorimeter with Filter 520 (maximum transmission).

Coenzyme Standard Curve: Six concentrations of sterile coenzyme, 0, 0.0075, 0.01, 0.025, 0.03, and 0.0375 µg., respectively, were added in triplicate to nine ml. of media described above in 50-ml. Erlenmeyer flasks, and sufficient sterile water added to bring the volume to 10 ml. The flasks were then inoculated with 0.1 ml. of the standard culture of *Hemophilus influenzae* previously described and incubated for 48 hours at 37°C.; 0.1 ml. of the 48-hour culture was then added to 8.5 ml. of water and the nitrite determined as described above.

The range of nitrite concentration which can be determined by diazotization and production of color by coupling is a narrow one. This technical limitation is further increased by the fact that the amount of nitrite produced by *Hemophilus influenzae* is relatively great for small increments of coenzyme. For these reasons it has been found best, in most instances, to limit the amount of culture taken for nitrite analysis to 0.1 ml. However, with certain strains of *Hemophilus influenzae* which reduce nitrates less effectively 0.2 to 0.5 ml. of the culture media may be required for an accurate determination. When one ml. or less of the medium is taken for analysis, even great turbidity of the culture medium owing to added test material does not interfere significantly with the photoelectric determination of color intensity.

Although standard curves of nitrite production with a given strain of *Hemophilus influenzae* are fairly constant from day to day, enough variation occurs to make it necessary to set up a new series of standards for each set of coenzyme test materials. Since *Hemophilus influenzae* responds indifferently to coenzyme I and coenzyme II,²²¹ determinations of the total V-factor have been expressed in terms of coenzyme I.

Preparation of Blood for V-Factor Determination: Blood was drawn under sterile precautions into sterile test tubes containing ammonium and potassium oxalates in the proportions suggested by Wintrob.²³⁹ The solution of oxalates was filtered to insure sterility and dried in the tubes at 65°C. (149°F.) before use. Preliminary dilution and laking of freshly drawn blood were performed with a volumetric 0.5 ml. pipette carefully wiped free of blood on the outer surface with sterile gauze and rinsed into 4.5 ml. of sterile water. From this 1:10 dilution further dilutions were made. Amounts of

diluted blood representing usually 0.005 to 0.001 ml. of whole blood were added to nine ml. of media in duplicate flasks, and as a rule a second series of similar dilutions was prepared and set up in the same manner. The volume of media and test material was brought to 10 ml. with sterile water and the flasks were inoculated with 0.1 ml. of the standard inoculum and incubated for 48 hours. At the end of the incubation period 0.1 ml. of each culture was mixed with 8.5 ml. of distilled water, according to the manner described for the preparation of the standard coenzyme curve, and the nitrite determined colorimetrically. The V-factor content of the blood dilution was read directly from the standard curve and expressed finally as micrograms of coenzyme per ml. of erythrocytes. The erythrocyte volume was determined on an aliquot of one ml. of blood in a Winetrob hematocrit tube.²⁴⁰ Previous methods for the microbiological determination of coenzyme have called for the heating of laked blood before it is added to the medium. In this study the results of a number of experiments have shown that heating the blood to 85°C. caused no change in the growth response of *Hemophilus influenzae*, hence was considered unnecessary.

Axelrod and Elvehjem's²⁴⁰ **Method for Microbiological Assay for Coenzyme I.** A yeast method, specific for the assay for coenzyme I has been employed by Axelrod and Elvehjem, adapted from similar methods by von Euler²⁴¹ and Myrbäch,²⁴² who noted that the addition of varying amounts of coenzyme I to a washed yeast preparation produced rates of fermentation which were proportional, within certain limits, to the amount of coenzyme I added.

The rate of carbon dioxide evolution is measured in a respirometer. Since no oxygen uptake is demonstrated, uncorrected readings are taken for carbon dioxide evolution. A significant amount of carbon dioxide is not absorbed by the liquid medium at the low partial pressure of carbon dioxide developed. The fermentation is carried out with air in the gas space. The flasks are shaken at 100 to 120 oscillations per minute in a water bath maintained at 30°C.(86°F.). After an equilibrium period of five minutes, the fermentation is allowed to proceed for one hour with readings taken every 10 minutes. The taps are opened momentarily when necessary. After an induction period of 10 to 20 minutes the rate of carbon dioxide evolution reaches a maximum which is maintained for 20 to 30 minutes. The rate then begins to decrease. Maximum rate of carbon dioxide evolution is proportional to the amount of coenzyme I present. Since the apozymase always contains traces of coenzyme I it is necessary to determine the rate of carbon dioxide evolution in the absence of any added coenzyme I and to subtract this basal value from all subsequent readings.

Apozymase: This term is used by von Euler and Myrbäch to designate a washed yeast preparation which contains all of the enzymes necessary for the yeast fermentation except coenzyme I. It is prepared from brewers' yeast. Filtered yeast is spread out in shallow pans and dried for three hours at room temperature with the aid of a fan. This dry yeast is stable for six months when stored in a refrigerator. Twenty grams of dry yeast are washed with 800 ml. of distilled water at room temperature for 30 minutes, the yeast centrifuged, and the procedure repeated twice. Washed yeast is then spread on glass plates and dried rapidly with a fan. The apozymase is ground finely and stored in a desiccator. The yield is approximately 10 grams. This is stable for about two weeks, but it is best to prepare the apozymase weekly.

The rate of fermentation is a function of the concentration of apozymase. Axelrod and Elvehjem found the saturation point to be about 300 mg. per Barcroft vessel, but 200 mg. per vessel gave satisfactory results.

Glucose: Eighty mg. glucose in 0.2 ml. buffer were placed in each flask.

Magnesium and Manganese Ions: One hundred mg. of each ion is added to each vessel as the chloride. These ions are necessary to establish maximum rate of fermentation. Manganese ions have the greater effect, but magnesium ions give a slight additional stimulation.

Hexose Diphosphate: The sodium salt is prepared from the calcium salt by treating with the calculated amount of sodium oxalate. The solution is brought to pH 6.2 and made to a concentration of 10 mg. of organic phosphorus per milliliter. Only traces of inorganic phosphorus are present. The rate of fermentation is a function of the amount of hexose diphosphate, and maximum rate is obtained in the presence of four mg. of organic phosphorus (equal to 22 mg. of sodium hexosediphosphate). Four tenths of a milligram of hexosediphosphate solution is added to each flask. This solution is stored in the frozen state.

Buffer—0.1 M Sodium and Potassium Phosphate, pH 6.2: A total of 0.8 mg. of buffer is added to each flask, making the final buffer concentration 0.04 M. This is optimum for the yeast used, but small variations in molarity cause significant decreases in the rate of fermentation. Yeasts vary with respect to the optimum phosphate molarity, so each yeast used for assay purposes must be tested.

Tissue extracts do not contain enough phosphate to alter the fermentation rate significantly. The optimum pH range for dry yeast fermentation is pH 6.2 to 6.6, and the pH must not vary from this range.

Coenzyme I: Coenzyme I is made up in a concentration of 50 μ g. per ml. with distilled water and is stored in the frozen state. Its activity remains constant for two months. A typical fermentation set-up is represented as follows:

Mg. and Mn. solution.....	0.1 ml.
Buffer solution.....	0.6 ml.
Glucose.....	0.2 ml.
Hexosediphosphate.....	0.4 ml.
Coenzyme I.....	} 0.7 ml.
Tissue extract.....	
Water.....	
Apozymase.....	200.0 mg.

A two-ml. volume is always used and two ml. of water are placed in the left-hand flask.

Addition of thiamine, cocarboxylase, riboflavin, yeast and muscle adenylic acid, and nicotinic acid had no effect upon the fermentation, therefore are not limiting factors in the assay. Coenzyme I is the only limiting factor. Coenzyme II is not determined by this method.

Coenzyme I is rapidly inactivated after death of the animal. Enzymatic destruction is rapid when normal structure is disrupted. This necessitates the rapid inactivation of enzymes to preserve coenzyme I. However, coenzyme I is heat-labile under certain conditions.

Extraction of Coenzyme I From Blood: Blood is obtained from guinea pigs and rats by heart puncture, from chickens by bleeding from external carotid artery, and from humans and dogs by venipuncture. Oxalate is used as an anticoagulant. Little loss of coenzyme I is encountered as long as the blood cells are intact; it is all confined in the corpuscles. Blood may be held overnight in a refrigerator without loss of potency.

Red cells are washed with isotonic saline and centrifuged long enough to insure maximum packing effect. Then two ml. are pipetted with five ml. of water at 80°C. (176°F.), stirred, immediately placed in a water bath at 80°C. for five minutes, and cooled. Cells are then homogenized by the method of Potter and Elvehjem.¹⁰⁸ Four-tenths to 0.8 ml. of supernatant liquid are suitable for carbon dioxide evolution measurements.

Extraction of Coenzyme I From Animal Tissue: Animals are sacrificed in the absence of any anesthesia; the tissue is rapidly removed and cut into thin slices and placed on slabs of solid carbon dioxide. The rate of inactivation of coenzyme I is greatly decreased as long as the tissue remains in the frozen state. Rat liver is stable for two weeks, though rat kidney and brains decrease in potency after one week.

Frozen tissues are ground to a fine powder in a mortar. Samples are weighed on a cold watch glass (0.5 to one gm.), washed into 25 ml. of boiling water with five ml. of warm water, boiled for two minutes, immediately cooled, made to volume and ali-

quots removed for assay. In the final concentration, 20 to 30 mg. of tissue are usually chosen, corresponding to 0.4 to 0.8 ml. extracts.

Snell and Wright's¹⁰⁶ Method for Microbiological Assay for Nicotinic Acid. The microbiological assay for nicotinic acid proposed by Snell and Wright has certain advantages over other methods. It has a sensitivity 20 to 100 times that possible with existing chemical methods. The test organism is nonpathogenic, and acid production may be used as an index of growth response to nicotinic acid, thus removing the limitations introduced when turbidity measurements are required in turbid or colored solutions.

The test organism is *Lactobacillus arabinosus* 17-5 (American Type Culture Collection No. 8014). Stab cultures are carried in yeast extract-glucose agar and are transferred monthly. After transfer, cultures are incubated at 30°C. (86°F.) for 24 to 48 hours, then held in a refrigerator. Inoculum for assay tubes is prepared by transferring from the stock culture to a sterile solution of the basal medium to which 0.1 µg. per ml. of nicotinic acid has been added. This culture is incubated at 30°C. for 18 to 36 hours, centrifuged, and resuspended in sterile saline solution.

The constituents of the basal medium are prepared as follows:

Acid-Hydrolyzed Casein: Fifty grams of "vitamin-free" casein are hydrolyzed with 250 ml. of 25-per cent sulfuric acid. Ordinary technical casein (and some "vitamin-free" caseins) contain considerable amounts of nicotinic acid. The mixture is autoclaved for 10 hours at 15 pounds pressure. The sulfuric acid is removed with barium hydroxide. Any excess of barium ion is carefully removed with a minimum amount of sulfuric acid and the solution is adjusted by dilution or evaporation to contain 100 mg. of dry matter per milliliter. It is preserved under toluene. Traces of nicotinic acid (and other vitamins) can be more completely removed from the hydrolysate by stirring the above solution at pH 3 with 10 mg. per ml. of active charcoal and filtering, but this is not recommended as a general procedure.

A simpler method of hydrolyzing casein is by use of constant boiling hydrochloric acid. Fifty grams of casein are dissolved in constantly boiling hydrochloric acid (equal volumes of concentrated HCl and water) and refluxing from eight to 10 hours. The acid is removed by repeated vacuum distillations, the sirup neutralized, and the volume adjusted with distilled water.

Treatment of acid hydrolysate of casein with activated charcoal for the removal of traces of nicotinic acid may result in a medium which does not permit maximum acid production. Isbell²⁷⁴ has shown that the addition of one µg. of p-aminobenzoic acid to 10 ml. of medium will restore the full activity to the medium. Pimelic acid, inositol, choline hydrochloride, thymus nucleic acid, adenosine, xanthin, and some organic preparations were also effective although purity of these compounds was in doubt. Thus, p-aminobenzoic acid is shown to be a growth factor for *Lactobacillus arabinosus* 17-5, and on this basis Lewis¹¹¹ developed an assay.

Cystine: A solution of cystine hydrochloride containing one mg. of cystine per ml. is prepared by suspending cystine in water and adding the least possible amount of hydrochloric acid to effect solution and then diluting to the required volume with water. It is kept under toluene.

Adenine, Guanine, and Uracil: A solution is prepared containing one mg. per ml. of each of these constituents. Solution is effected by prolonged heating in the presence of a few drops of hydrochloric acid. It is stored in the refrigerator and is renewed at frequent intervals.

Thiamine, Calcium Pantothenate, and Pyridoxine: Stock solutions are prepared containing 100 µg. per ml. dissolved in distilled water. They are stored in the refrigerator and renewed at frequent intervals.

Riboflavin: A solution of riboflavin containing 100 µg. per ml. is prepared in 0.02 N acetic acid and kept in the refrigerator. Unnecessary exposure to light should be avoided and a fresh solution prepared at frequent intervals.

Biotin: Any concentrate which is free from significant amounts of nicotinic acid may be used. Suitable concentrates can be obtained by following the Kögl and Tönnes procedure.¹²⁶ A convenient procedure has been outlined by Snell and Wright. Crystal-

line preparations of biotin and its methyl ester, recommended for use whenever possible, are now available commercially. The free acid should be used, since this organism, unlike yeast, is unable to utilize the methyl ester. A suitable hydrolysis procedure for preparing free biotin from the methyl ester has been described by du Vigneaud *et al.*¹⁴⁹

Inorganic Salts: Solutions A and B are prepared according to directions given in the instructions for the riboflavin assay.

BASAL MEDIUM *

Acid-hydrolyzed casein.....	0.5	per cent

pH adjusted to 6.6 to 6.8		

*These concentrations are based on the final composition of the medium when the tubes are ready to sterilize. It should be made up in twice this concentration for dispensing in the tubes.

Some investigators have experienced difficulty in obtaining low blanks when using Snell and Wright's method. Tepley, Strong, and Elvehjem²⁴³ observed some of the constituents of the medium, such as casein, biotin concentrates, and cystine preparations might be sources of contamination. Vitamin-free casein or acid-washed casein, prepared according to the method of Arnold and Elvehjem,²⁴⁴ gave satisfactory blanks. Extraction of the casein with alcohol reduced the blank titration to about 0.5 ml. of N/10 alkali. High blank values may be overcome by preparing the casein hydrolysate by hydrochloric acid hydrolysis of previously purified casein, and subsequently treating the hydrolyzate with active charcoal.²⁵²

Nicotinic acid and its amides have equal activities for the organism. Cozymase when assayed was found to contain 17 per cent of nicotinamide (theoretically, 18 per cent). Trigonelline is inactive. Nicotinuric acid shows the same activity as its theoretical equivalent of nicotinic acid.

Preparation of Samples for Analysis: The treatment of the sample for assay will vary somewhat with the material to be tested. Animal tissues should be finely ground and extracted with a large volume of water at 15 pounds pressure for 30 minutes followed by filtration. Color or slight turbidity in the test sample does not influence the results. Preliminary autolysis of the tissue sample does not increase the extracted nicotinic acid, as is reported in the case of biotin¹²⁸ and pantothenic acid.¹¹⁰ Extraction with alkali does not increase the assay values. Milk powder and animal tissue show essentially the same apparent nicotinic acid content after treatment by enzyme digestion or hot extraction with sulfuric acid or sodium hydroxide.²⁴⁵

Enzymatic liberation of vitamins from animal tissue has been reported satisfactory for routine assays.^{245, 246} It has been used for extraction of

243. Tepley *et al.* 1942. *J. Nutr.* 23, 417-423.

244. Arnold and Elvehjem. 1938. *Idem* 15, 429.

246. Williams *et al.* 1941. *Univ. of Texas Pub.* 4137 and 4237.

vitamins from plant tissue, though some doubt exists as to the proper pretreatment for liberating nicotinic acid.

Cheldelin and Williams²⁴⁵ showed autoclaving in a large volume of water for 30 minutes and enzymatic liberation gave essentially the same nicotinic acid values for green peas. On the other hand, they reported a 35 to 40 per cent greater recovery of nicotinic acid from lima beans and black-eyed peas when hydrolyzed by 30 minutes autoclaving in 1 N sulfuric acid. Cereal products have been more extensively studied. Snell and Wright relied upon water to extract the nicotinic acid without removing substances reported by Kodicek²⁴⁷ to interfere with chemical determinations of the vitamins. These substances are extracted by alkali treatment. When grain is sufficiently finely ground, water extracted nearly as much nicotinic acid as did eight per cent sodium hydroxide. However, Cheldelin, and Williams,²⁴⁵ Melnick,²⁴⁸ and Andrews, Boyd, and Gortner²⁴⁹ have reported aqueous extraction gives variable results, depending on the severity of treatment. Repeated aqueous extraction by autoclaving gives results approaching those obtained after alkaline hydrolysis. Oser, Melnick, and Siegel,²⁵⁰ using a chemical method, reported alkaline extraction to give higher nicotinic acid values than water extraction, since treatment of aqueous extracts with alkali raises the apparent nicotinic acid content to that found by direct extraction with sodium hydroxide.

Andrews, Boyd, and Gortner,²⁴⁹ using the Snell and Wright method, have also noted wide difference in nicotinic acid values depending on pretreatment of sample prior to assay. Aqueous and 0.1 N sulfuric acid extraction gave the same value, whereas 1.5 per cent sodium hydroxide, 3 N hydrochloric acid extraction, and alkaline hydrolysis of aqueous extracts gave nearly 100 per cent greater value. Regardless of the type of extraction procedure used, recovery experiments of added nicotinic acid were quantitative. Both alcohol-soluble and alcohol-insoluble fractions of whole-wheat flour exhibited nicotinic acid activity which could be enhanced by alkali treatment. Adsorption of nicotinic acid and the unknown factor occurred simultaneously on Lloyd's reagent. Of milled wheat-products only wheat germ was found to behave similar to animal tissues and yeast in giving practically the same nicotinic acid values with aqueous and alkaline extraction. This fact suggested to Andrews *et al.*²⁴⁹ that two forms of nicotinic acid are involved, one being present in "living" or potentially living tissue and being more readily available than that requiring alkali to liberate it and another found in "storage tissue," such as bran and flour which are present in wheat primarily to protect the germ and supply it with food during germination.

Tepley, Strong, and Elvehjem²⁴³ have used strong acid or alkali to give complete liberation of nicotinic acid from cereal. For most products

they found water satisfactory, though they relied on alkaline hydrolysis to insure complete extraction from fruits and vegetables.

Krehl, Strong, and Elvehjem²⁵² have suggested the following extraction procedure. Sodium hydroxide proved undesirable for general use on account of soap formation with high-fat samples.

Dry materials are finely ground and fresh materials are mechanically homogenized in water with a Waring Blendor or a Potter-Elvehjem homogenizer. One gram of material is suspended in 50 ml. N hydrochloric or sulfuric acid and the suspension is autoclaved for 20 minutes at 15 pounds pressure. The cooled mixture is adjusted to pH 6.6 to 6.8 with N sodium hydroxide, and diluted to such a volume that each milliliter contains approximately 0.05 microgram of nicotinic acid. Filtration is unnecessary but does no harm. Water-soluble materials are dissolved in the acid, autoclaved, neutralized, and diluted as above.

Results of investigations comparing microbiological and chemical methods for assaying for nicotinic acid in cereals have been reported by Melnick²⁴⁸ and Cheldelin and Williams.²⁴⁵ Significant increases were noticed in apparent nicotinic acid content of cereals after acid or alkaline hydrolysis in comparison with aqueous or enzyme hydrolysis. Clear extracts obtained by enzymatic hydrolysis of bread or flour showed increased nicotinic acid content after hydrolysis with acid or alkali. Green, Black, and Howland²⁵¹ reported substantial agreement of results of the chemical and microbiological assay method of Snell and Wright when applied to commercial B-complex products, such as yeast, yeast extract, liver extract, and rice-bran concentrate. Hydrolysis of sample with strong acid often gave slightly higher values than aqueous extracts particularly in products of cereal origin and their concentrates. Trigonelline, the betaine of nicotinic acid, has been suggested as the unknown substance. Andrews *et al.*²⁴⁹ observed that when trigonelline was subjected to aqueous or alkaline extraction, no nicotinic acid was recovered. In presence of urine, trigonelline has been shown to be partially converted to a substance giving the color reactions of nicotinic acid. Strong alkali will give greater conversion. Cheldelin and Williams observed no conversion after autoclaving 30 minutes in presence of 2 N sodium hydroxide. Certain substances, such as asparagine, accelerated the reaction. Ammonium sulfate, urea, glutamine, β -alanine, acetamide, and urotropin can also replace asparagine under conditions of alkaline hydrolysis. Cheldelin and Williams believed that under these conditions, the high conversions obtained in presence of asparagine or β -alanine may be due to slow production of ammonia (or $-\text{NH}_2$ groups) in the reaction mixture. On the other hand, the apparent increase in nicotinic acid in cereal products produced by acid hydrolysis cannot be explained by conversion of trigonelline. Large amounts of trigonelline failed to affect the apparent nicotinic acid content of whole-wheat bread. Addition of reducing agents also failed to produce significant increases. Melnick expressed doubt that trigonelline was involved. Dried cowpeas relatively rich in trigonelline did not show the great increase in apparent nicotinic acid after acid or alkaline hydrolysis. Results

of the methods of Melnick, Oser, and Siegel,²⁵³ Dann and Handler,²⁵⁴ and Melnick and Field²⁵⁵ agree substantially with those of Snell and Wright's method when comparable methods of sample preparation were used. Also the microbiological methods of Darfman, Koser, Horwitt, Beckman, and Saunders²²⁸ gave good results when compared with Snell and Wright's procedure. The Bina, Thomas, and Brown²⁵⁶ procedure was unsatisfactory. Using the Dann and Handler chemical method, Cheldelin and Williams observed substantial agreement in results with the microbiological assay procedure when parallel methods of extraction of nicotinic acid were used. With dry yeast, however, the chemical method gave satisfactory results only after sulfuric acid hydrolysis.

Thus in summary for cereal products at least, mild aqueous extraction gives the lowest nicotinic acid values. Predigestion of the sample with enzymes gives only slightly higher figures. Maximum values, more than twice those resulting from aqueous extraction, were obtained on acid or alkaline extracts. These values are approximated in the assays of exhaustive aqueous extracts. Melnick has stated: "It is impossible to state at the present time exactly how much of the total nicotinic acid in cereal products is the unknown nicotinic acid derivative. Because of the ready hydrolysis of the compound, it is conceivable that some conversion to nicotinic acid occurs even in mild aqueous extracts during the subsequent sterilization (autoclaving) of the test solutions prior to inoculation with microorganisms."

A statement as to the proper treatment for assay, whether by chemical or microbiological procedures, must await the determination of the biological activity of the unknown substance in animals. A little evidence thus far accumulated suggests that it is biologically active. Morgareidge²⁵⁷ reported that a dog black-tongue curative assay conducted on a rice-bran concentrate gave a value of 1.65 mg. of nicotinic acid per gram (Waisman, Mickelson, McKibben, and Elvehjem²⁵⁸), while microbiological assay values were 0.83 mg. prior to and 1.65 mg. after alkaline hydrolysis.

Brown, Thomas, and Bina²⁵⁹ have reported much lower nicotinic acid values on certain wheat fractions after oxidation with hydrogen peroxide than have been reported by others. Certain chromogens encountered in chemical assays were also eliminated. These workers claimed the lower values were more nearly representative of the anti-pellagra activity of these substances. Krehl, Strong, and Elvehjem²⁵² repeated the work on whole wheat and were unable to corroborate their findings.

Krehl, Strong, and Elvehjem's Modification of the Snell and Wright Microbiological Assay for Nicotinic Acid and Nicotinamide. Certain difficulties have been encountered in the Snell and Wright method, namely, relatively high blanks resulting from inefficient removal of nicotinic acid from the acid-hydrolyzed casein, and variations in the

standard curve implying a lack of specificity of the assay. An improved medium has been proposed by Krehl, Strong, and Elvehjem²⁵² which supports a greater acid production by *Lactobacillus arabinosus* 17-5 and gives greater reliability and reproducibility of assay results. The glucose and sodium acetate concentrations were increased to two per cent, resulting in a definite improvement in the bacterial response to nicotinic acid. Two per cent glucose alone had no effect. Cystine concentration was doubled as certain workers had reported a linear standard curve over a wider range and higher acid production. Since activated-charcoal treatment of acid-hydrolyzed casein sometimes creates a deficiency in p-aminobenzoic acid, this vitamin has been incorporated in the basal medium. Biotin concentration has been reduced from 0.4 to 0.2 part per billion. The new medium in its final concentration is shown here. For dispensing into culture tubes, it is prepared in double this concentration.

Acid-hydrolyzed casein.....	0.5 per cent
Tryptophane.....	0.01 per cent
Cystine.....	0.02 per cent
Glucose.....	2.0 per cent
Sodium acetate.....	2.0 per cent
Calcium pantothenate.....	0.1 p.p.m.
Thiamine chloride.....	0.1 p.p.m.
Pyridoxin.....	0.1 p.p.m.
Riboflavin.....	0.2 p.p.m.
Biotin.....	0.2 p.p.billion
p-aminobenzoic acid.....	0.1 p.p.m.
Adenine.....	10.0 p.p.m.
Guanine.....	10.0 p.p.m.
Uracil.....	10.0 p.p.m.
Inorganic salts, Solutions A and B, 10 ml. each per liter of basal medium	

Unless otherwise specified, the preparation of the various constituents of the basal medium is the same as given by Snell and Wright.

Acid-Hydrolyzed Casein: One hundred grams of "vitamin-free" casein are twice extracted by stirring 15 minutes at room temperature with two to three volumes of 95-per cent ethyl alcohol and filtered. The casein is then gently refluxed with 300 ml. of concentrated hydrochloric acid for 16 to 20 hours. The casein hydrolyzate is concentrated to a paste *in vacuo* from a 70 to 80°C. (158 to 176°F.) water bath, 200 ml. of water are added, and the concentration repeated. The residue is dissolved in about 700 ml. of water, adjusted to pH 4 (yellow-green to bromocresol green, outside indicator) with saturated sodium hydroxide solution, 20 grams of an activated charcoal (Norite A or Darco G-60) are added, and the mixture is stirred for one hour at room temperature. The charcoal is removed by gravity filtration, the pH adjusted to 6.6 to 6.8, and the filtrate diluted with distilled water to 1,000 ml. Each milliliter is equivalent to 100 mg. of the original casein. The final solution should be no darker than a pale straw color. Any sediment occurring in the casein hydrolyzate on standing may in general be eliminated by autoclaving for one hour at 15 pounds pressure.

Biotin: The contents of an ampoule containing 25 micrograms of biotin as the free acid are diluted to 250 ml. so that each milliliter contains 0.1 microgram. One ml. of inorganic salt Solution A is added as the solution is being diluted to volume.

When biotin methyl ester is used, the contents of a 25-microgram ampoule are added to 50 ml. of 0.1 N hydrochloric acid and autoclaved for one hour at 15 pounds pressure. One ml. of inorganic salts Solution A is added, the pH is adjusted to 6.6 to 6.8, and the volume is made to 236 ml. Each milliliter, therefore, contains 0.1 microgram of biotin, since 25 micrograms of biotin methyl ester theoretically yields 23.6 micrograms of the free acid on hydrolysis. The use of 0.1 N hydrochloric acid is specified because autoclaving of neutral solutions of biotin methyl ester did not bring about complete hydrolysis.

Since certain fatty acids have been shown to interfere with microbiological determinations of riboflavin and pantothenic acid where *Lactobacillus casei* ϵ is used as the test organism, Krehl, Strong, and Elvehjem²⁵² have reported the effects of certain fatty acids on the nicotinic acid assays employing *Lactobacillus arabinosus* 17-5 as the test organism. Oleic, stearic, and palmitic acids were without effect, while linoleic tended to give slightly high assay values.

Atkin, Schultz, Williams, and Frey's Method for Differentiating Nicotinic Acid and Nicotinamide by Microbiological Assay. Nicotinic acid and its amide have equal vitamin potencies in animals and microorganisms, consequently the method of Snell and Wright determines the combined effect of both compounds. With the advent of commercial preparation designed for therapeutic uses, the assay of either of these compounds may be of interest. Atkin, Schultz, Williams, and Frey²⁶⁰ have reported a method based on the Hofmann reaction,²⁶¹ e.g., the action of bromine and potassium hydroxide upon amines. When applied to nicotinamide, β -aminopyridine is formed,²⁶² which is apparently inactive microbiologically.

To one ml. of a solution containing one mg. of nicotinamide add five ml. of water and one one ml. of saturated bromine water, followed by three ml. of 30-per cent potassium hydroxide. Allow the solution to stand at room temperature for 20 minutes and then steam for 20 minutes. Cool, add an excess of 10 N sulfuric acid (blue to Congo red), then remove any excess of bromine by use of a four-per cent solution of sodium bisulfite. Use an outside starch iodine indicator to determine the end point. The final solution after neutralizing is assayed by the Snell and Wright procedure. Thus, only nicotinic acid is determined after treatment and nicotinamide may be determined by estimating the vitamin activity before and after the treatment.

Another microbiological procedure for assaying for nicotinic acid employing *Lactobacillus casei* ϵ has been proposed by Landy and Dicken.⁶⁸ It is given later in this chapter.

p-AMINOBENZOIC ACID

The vitamin activity of p-aminobenzoic was discovered by Ansbacher.²⁶³ It is a growth-promoting factor for chicks and a chromotrichia factor for rats. Siene²⁶⁴ reported nutritional achromotrichia in man to be favorably influenced by the compound. Woods and Fildes²⁶⁵ had previously observed in *in vitro* experiments an antisulfanilamide action by p-aminobenzoic acid. Woods²⁶⁶ showed similar activity by a factor in yeast extracts and suggested this compound. Rubbo and Gillespie²⁶⁷ isolated it from yeast. Fildes²⁶⁸ suggested that p-aminobenzoic acid is a metabolite for bacteria.

A semi-quantitative method for assaying for p-aminobenzoic acid, using *Clostridium acetobutylicum* as the test organism, has been employed by Rubbo and his colleagues.²⁶⁹ This vitamin is synthesized by various microorganisms. Landy, Larkum, and Oswald,²⁷⁰ using *Acetobacter suboxydans*, believed that was an "essential metabolite" synthesized by many bacteria.

Landy and Dicken's Method for Assaying for p-Aminobenzoic Acid. This vitamin was shown to be a growth factor for *Acetobacter suboxydans* by Lampen, Underkofler, and Peterson.²⁷¹ From these facts, Landy and Dicken²⁷² reported a microbiological assay procedure using *Acetobacter suboxydans* (American Type Culture Collection, No. 621) as the test organism.

The test organism is carried on yeast-extract glycerol agar (0.5 per cent Bacto yeast extract, five per cent glycerol, pH 6). Stock cultures are transferred at monthly intervals and are refrigerated in the interim. Inoculum for assays is prepared by transfer from the stock culture to a flask of basal medium to which has been added 0.5 μ g. of p-aminobenzoic acid. The inoculum culture is incubated at 30°C.(86°F.) for 24 hours prior to use and is transferred daily from the preceding liquid culture, being returned to a stock culture at weekly intervals.

The composition of the basal medium, in twice the desired final concentration, is as follows:

Casein hydrolyzate*	0.6 gm.
Glycerol.....	10.0 gm.
Tryptophane.....	20.0 mg.
Cystine.....	15.0 mg.
Potassium hydrogen phosphate, K_2HPO_4	100.0 mg.
Potassium hydrogen phosphate, KH_2PO_4	100.0 mg.
Magnesium sulfate, $MgSO_4 \cdot 7H_2O$	40.0 mg.
Sodium chloride, NaCl.....	2.0 mg.
Ferrous sulfate, $FeSO_4 \cdot 7H_2O$	2.0 mg.
Manganese sulfate, $MnSO_4 \cdot 2H_2O$	2.0 mg.
Calcium pantothenate.....	200.0 μ g.
Nicotinic acid.....	200.0 μ g.
Distilled water to 100 ml.	
pH adjusted to 6.0	

* This purified casein hydrolyzate may be obtained from the Res. Labs. of S.M.A. Corp., Chagrin Falls, Ohio. Other purified casein hydrolyzates are equally effective.

Landy and Streightoff²⁷³ observed that when the casein hydrolyzate employed in the basal medium is treated with Darco G-60 charcoal (10 per cent by weight) at pH 2.5 for 30 minutes, growth response to lower concentrations of p-aminobenzoic acid is variable and generally subnormal. Adenine, guanine, and xanthine, 50 μ g. each per 10 ml. culture, were found effective in overcoming this variability, and sensitivity of the test organism to the vitamin was increased. This is particularly true below 0.03 μ g. of p-aminobenzoic acid per tube. Adenine, in quantities of 150 μ g. per culture, can replace the combination of the three purine bases, though more uniform results were obtained in the presence of the three purines. Uracil was inactive.

Assay Procedure: Five ml. of the basal medium and dilutions of material under test made up to five ml. with distilled water are placed in 50-ml. Erlenmeyer flasks. *Acetobacter suboxydans* is an obligate aerobe. Small Erlenmeyer flasks permit heavier growth of 10-ml. cultures than do the usual bacteriological culture tubes. Similarly, a set of reference flasks is prepared containing from 0.01 to 0.10 μ g. of p-aminobenzoic acid. Blanks containing no p-aminobenzoic acid are included. The flasks are plugged with cotton and autoclaved at 15 pounds pressure for 15 minutes. After cooling they are inoculated with a suspension of *Acetobacter suboxydans*. A 24-hour culture, grown as described above, is centrifuged and washed; cells are resuspended in 15 ml. of saline solution, a drop of which serves as inoculum for each flask. Flasks are incubated at 30°C. for 48 hours. Following incubation, 10 ml. of distilled water are added to each flask to dilute the culture suitably for measurement of turbidity and the contents are thoroughly mixed by shaking. Growth response to increments of p-aminobenzoic acid

271. Lampen, Underkofler, and Peterson. 1942. J. Biol. Chem. 146, 277-278; J. Bact. 1943. (In press.)

272. Landy and Dicken. 1942. J. Biol. Chem. 146, 109-114.

273. Landy and Streightoff. 1943. Soc. Expt. Biol. and Med. Proc. 52, 127-128.

is determined by measurements of turbidity with a photoelectric colorimeter. From a standard curve so prepared, the p-aminobenzoic acid test sample may be calculated. Results from at least three assay levels should be averaged for the final results.

Preparation of Sample for Assay: Materials which are soluble in water are assayed without further treatment. Insoluble materials, such as food stuffs, grains, and animal tissues, are finely divided, extracted with 10 to 20 volumes of water at 15 pounds pressure for 30 minutes, and centrifuged or filtered. Such treatment has yielded maximum assay values. Body fluids require special handling, since many have been found to inhibit growth of the test organism. The inhibitory action of blood, spinal fluid, ascitic fluid, and urine is readily overcome by autoclaving. Blood is prepared for assay as follows: The sample is laked with an equal volume of distilled water and autoclaved. Three volumes of water are added to the autoclaved blood while hot, and the sample is shaken for several minutes to dispense and extract the protein precipitate. The suspension is centrifuged and the supernatant filtered to give a clear extract suitable for assay. Other body fluids may be prepared for assay by the above procedure. They do not show inhibition and give values in good agreement at various levels.

Landy and Dicken have shown the growth test is specific for p-aminobenzoic acid. Substitution, whether in the amino or carboxy group, sharply reduces or completely removes biological activity.

Lewis Method for Microbiological Assay for p-Aminobenzoic Acid. This method uses *Lactobacillus arabinosus* 17-5 (American Type Culture Collection, No. 8014). Isbell²⁷⁴ reported submaximum growth of the organism in the nicotinic acid assay medium of Snell and Wright unless supplements of this compound are added. From this information Lewis¹¹¹ has proposed the following assay method.

The following basal medium is used, the composition of which is indicated in its final dilution. For assay purposes it is prepared in double this concentration.

Glucose.....	1.0 per cent
Norite-treated, acid-hydrolyzed casein.....	0.5 per cent
l-cystine.....	0.01 per cent
l-tryptophane.....	0.01 per cent
Sodium acetate.....	0.6 per cent
K ₂ HPO ₄ ·3H ₂ O.....	0.05 per cent
KH ₂ PO ₄	0.05 per cent
MgSO ₄ ·7H ₂ O.....	0.02 per cent
NaCl.....	0.001 per cent
FeSO ₄ ·7H ₂ O.....	0.001 per cent
MnSO ₄ ·4H ₂ O.....	0.001 per cent
Adenine.....	10.0 p.p.m.
Guanine.....	10.0 p.p.m.
Uracil.....	10.0 p.p.m.
Thiamine.....	0.1 p.p.m.
Riboflavin.....	0.2 p.p.m.
Pantothenic acid.....	0.1 p.p.m.
Nicotinic acid.....	0.4 p.p.m.
Pyridoxine.....	0.1 p.p.m.
Biotin.....	0.0004 p.p.m.

The components are prepared as follows:

Norite-Treated, Acid Hydrolyzed Casein: One hundred grams of vitamin-free casein are hydrolyzed under a reflux for nine hours with 1,000 ml. of 6 N hydrochloric acid. To remove most of the hydrochloric acid the mixture is then concentrated *in vacuo* to a thick sirup, dissolved in water, and reconcentrated. The sirup is diluted to 900 ml., adjusted to pH 3 with concentrated sodium hydroxide, and stirred for 30

274. Isbell. 1942. J. Biol. Chem. 144, 567-568.

minutes with nine grams of norite A (Pfanstiehl). The activated carbon is removed by filtration through a Whatman No. 3 filter paper, and the norite treatment and filtration repeated. The filtrate is adjusted to pH 6.8 with concentrated sodium hydroxide, and is diluted to 1,000 ml. The hydrolyzed casein is stored in the refrigerator. On standing, precipitation of tyrosine occurs. No difference in results has been noticed whether this precipitate is discarded or whether it is included in the basal medium.

Adenine, Guanine, and Uracil: A solution containing one mg. per ml. of each of these chemicals is convenient. One hundred mg. of uracil, 124 mg. of guanine hydrochloride, and 174 mg. of adenine sulfate are suspended in a small volume of water, two ml. of hydrochloric acid are added, and the mixture is heated to solution and then diluted to 100 ml.

Vitamin Supplement: A solution containing one mg. of thiamine, two mg. of riboflavin, one mg. of pantothenic acid, four mg. of nicotinic acid, one mg. of pyridoxine, and four μ g. of biotin per 100 ml. is prepared. Pure, synthetic vitamins are used in all cases except that of biotin. Here crystalline biotin is used. The solution is stored in the refrigerator and is renewed monthly. This is conveniently done by diluting more concentrated solutions of the individual vitamins, which are stable for longer periods. Exposure of riboflavin to light should be minimized.

For a liter of medium, use 20 gm. glucose, 12 gm. sodium acetate, 200 mg. l-tryptophane, 200 ml. l-cystine solution, 100 ml. hydrolyzed casein, 20 ml. of adenine-guanine-uracil mixture, 20 ml. of vitamin supplement, 10 ml. each Solutions A and B, inorganic salts (Snell and Strong⁶⁶), and adjusted to pH 6.8.

The assay is carried out according to the methods used in the other assay procedures employing *Lactobacillus* cultures. Five-ml. aliquots of the basal medium are dispersed into culture tubes, appropriate aliquots of p-aminobenzoic acid solution for the standard curve and solutions or suspensions to be assayed are added, and the total volume made to 10 ml. with distilled water. The tubes are plugged with cotton and autoclaved at 15 pounds pressure for 10 to 15 minutes. The tubes are cooled, inoculated, and incubated at 30°C. (86°F.).

The stock culture of *Lactobacillus arabinosus* 17-5 is carried in yeast extract-glucose agar stab culture. Transfers are made monthly, incubated at 30°C. for 24 hours, then stored in the refrigerator. For subculturing, the basal medium is diluted with an equal volume of water to which one millimicrogram of p-aminobenzoic acid per 10 ml. has been added. The organism is incubated in this medium for 24 hours at 30°C., the cells are centrifuged and resuspended in the original volume of 0.9 per cent sodium chloride solution. The assay tubes are inoculated from this suspension.

The assay range is approximately 0.15 to 0.5 micrograms of p-aminobenzoic acid per tube. A standard solution containing 10 μ g. per ml. of p-aminobenzoic acid is diluted to contain 0.10 millimicrograms per ml. This standard is dispensed in 0, 1, 1.5, 2, 2.5, 3, 3.5, 4, 4.5, and 5 ml. aliquots. Two or more replicates are used at each level. A standard curve is prepared, plotting the titratable acidity produced by the test organism against the level of the vitamin.

Preparation of Samples for Assay: Lewis made only preliminary studies of methods for liberating p-aminobenzoic acid from biological materials. The method has been applied only to water-soluble materials, water-soluble extracts from natural products, and yeast suspensions. In some cases samples were autoclaved in 1 N sodium hydroxide for 30 minutes at 13.5 pounds pressure, after which they were neutralized and assayed. In many of these cases increased p-aminobenzoic acid assays were found. Autoclaving solutions of the vitamin in water or 0.1 N sodium hydroxide at 10 pounds pressure for 10 minutes resulted in no destruction, whereas under the same conditions solutions in 1 N sodium hydroxide gave 10 per cent inactivation while solutions in 10 N sodium hydroxide gave 50 per cent inactivation. Sulfuric acid in concentrations from 0.1 to 10 N gave approximately 30 per cent inactivation, as did similar solutions in hydrochloric acid. Repeated autoclaving was relatively more detrimental under acidic than under alkaline conditions.

Specificity of the Method: Samples of o- and m-aminobenzoic acid had only slight activity which perhaps could be attributed to impurities of p-aminobenzoic acid. Rubbo *et al.*²⁰⁰ found the sodium salt, ethyl ester, and p-aminobenzaldehyde to possess activity for *Clostridium acetobutylicum* approximately equal to that of p-aminobenzoic acid. They also found the benzoyl derivative, the diethylaminomethyl ester, and p-nitrobenzoic acid to have approximately 10 per cent of the activity of the vitamin. p-Aminophenylacetic acid had about 10 times the activity of the vitamin for *Clostridium acetobutylicum*.

By means of x-ray or ultraviolet light treatment, Beadle, Tatum, Horowitz, and Bonner²⁷⁵ induced genetic changes in *Neurospora crassa* which, in some cases, have been concerned with vitamin synthesis. One mutant lost the ability to synthesize the thiazole fraction of the thiamine molecule. Another cannot combine the thiazole and pyrimidine moieties. Other mutants have not been able to synthesize pyridoxin, nicotinic acid, p-aminobenzoic acid, pantothenic acid, and choline. Each of these mutants responds quantitatively to the addition to the culture medium of the vitamin which cannot be synthesized. The response can be measured either as dry weight attained under standard conditions or as rate of advance of a mycelial front along a special growth tube containing an agar medium.

Thompson, Isbell, and Mitchell's Method for the Microbiological Assay for p-Aminobenzoic Acid. Using a strain designated by Beadle and Tatum as *Neurospora crassa* p-aminobenzoicless No. 1633, Thompson, Isbell, and Mitchell²⁰¹ have developed an assay technic for this vitamin. The basal medium consists of the following components:

Ammonium tartrate.....	5.0 gm.
Potassium dehydrogen phosphate.....	1.0 gm.
Ferric chloride.....	5.0 mg.
Ammonium nitrate.....	1.0 gm.
Magnesium sulfate heptahydrate.....	0.5 gm.
Sodium chloride.....	0.1 gm.
Calcium chloride.....	0.1 gm.
Sucrose.....	15.0 gm.
Biotin.....	4.0 μ g.
Washed agar.....	20.0 gm.
Acid-hydrolyzed vitamin-free casein.....	1.0 gm.
Enzyme digested beef liver extract.....	0.5 gm.
Enzyme digested beef muscle extract.....	0.1 gm.
Charcoal-treated yeast extract.....	0.1 gm.
Distilled water.....	1.000 ml.

Acid-Hydrolyzed Vitamin-Free Casein: Fifty grams of vitamin-free casein are hydrolyzed by boiling under reflux for 10 hours in 500 ml. 6 N hydrochloric acid. The acid is removed by repeated vacuum distillation. After adjusting the pH to 3 and the volume to 500 ml., five grams of activated charcoal (Darco G-60) are added, the suspension shaken for 15 minutes, and filtered to remove the charcoal. The pH is then adjusted to 7 and the solution is preserved under toluene.

Enzyme-Hydrolyzed Beef Liver and Muscle: Ten grams of fresh beef liver or muscle, finely ground, are suspended in 50 ml. of acetate buffer solution, pH 4.5, containing 0.1 gram clarase and caroid. After 24 hours' autolysis under benzene, the benzene is removed by steaming, and the extract filtered.

Charcoal-Treated Yeast Extract: Ten grams of Difco yeast extract are dissolved in 100 ml. distilled water and adjusted to pH 3. Two grams of Darco G-60 are added and the suspension shaken for 15 minutes, filtered, and adjusted to pH 7.

275. Beadle, Tatum, Horowitz, and Bonner. 1943. Abstracts, American Chemical Society Meeting, April 12-15.

Washed Agar: Commercial agar preparations often contain considerable quantities of vitamins, including p-aminobenzoic acid, which is removed by washing 15 to 20 times with distilled water in a 24- to 48-hour period.

The stock culture of the *Neurospora crassa* mutant is carried on the basal medium containing 0.05 μ g. of p-aminobenzoic acid per 10 ml.

The inoculum is prepared by thoroughly dispersing a loopful of spores in one to two ml. of sterile liquid agar medium identical in composition with the assay medium except for addition of five μ g. p-aminobenzoic acid. This is poured into sterile Petri dishes, incubated 16 hours at 30°C., and then stored in a refrigerator until used. During this time the spores will have germinated and incipient mycelium, uniformly distributed, will be just visible to the naked eye.

The Assay: Standard p-aminobenzoic acid solutions and solutions for assay are pipetted into a test tube and diluted to one ml. To this are added 15 ml. of the agar basal medium, the tube is autoclaved for 15 minutes and the contents immediately transferred to sterile Petri dishes. When the plates are cool they are inoculated by placing blocks of agar cut from the inoculum culture plates, with sterile eight-mm. cork borers fitted with a plunger for extruding the agar block. The agar block should be placed in the center of the plate and care should be exercised that the inoculum block be nearly round, for its slope affects the slope of the colony formed. Each plate is incubated at 30°C. for 20 hours, after which the diameter of the mold colony is measured with calipers. The size of the colony is in proportion to the amount of p-aminobenzoic acid present.

For establishing the standard curve, similar plates are prepared containing four to 45 μ g. of the vitamin and incubated with the assay plates.

Preparation of Samples for Assay: Data secured by Mitchell, Isbell, and Thompson's²⁷⁶ method suggest that aqueous extraction of the vitamin, as employed by Landy and Dicken, yields only a fraction of the total contained. Enzymatic hydrolysis, according to the method of Cheldelin *et al.*²⁷⁷ or autolysis (Blanchard²⁷⁸) are not reliable in liberating all of the vitamin. Alkaline hydrolysis (0.1 to 5 N NaOH) destroys about 15 per cent of the vitamin in pure solution and presumably about the same extent in tissue. Yet 6 N sulfuric acid gives maximum extraction despite about 15 per cent destruction, and Thompson *et al.* relied on this procedure, carried out as follows:

One to five grams of sample, finely ground, to which are added five ml. of 6 N sulfuric acid per gram, are autoclaved at 15 pounds pressure for one hour. The acid is neutralized with barium carbonate; the resulting barium sulfate and other undissolved material are filtered off. The pH is then adjusted to neutrality. Neutralizing the sulfuric acid with sodium hydroxide or ammonium hydroxide is not permissible as excessive amounts of salts are toxic to the test organism.

Many substances were found to contain bound p-aminobenzoic acid liberated only by acid hydrolysis. Notable among these were animal tissue, urine, wheat, egg, spinach, carrots, and potatoes; yeast and sweet potatoes have 10 per cent or less of the "bound" form.

The organism is apparently specific in its requirements for p-aminobenzoic acid. Beadle and Tatum²⁰⁰ tested a large number of compounds none of which were active over a fraction of one per cent of the activity of the vitamin. Thompson *et al.*²⁰¹ noticed that the amide had 0.03 per cent of the activity of the p-aminobenzoic acid.

Landy and Dicken's⁶⁸ Method for Assaying for Presence of Certain Members of the Vitamin-B Complex. This method, which involves use of *Lactobacillus casei* ϵ , may be used for assaying for riboflavin, pantothenic acid, biotin, folic acid, pyridoxin, and nicotinic acid. In the assay procedure the particular vitamin under assay is omitted from the basal medium. Proper amounts are used for preparation of the respective standard curves.

COMPLETE MEDIUM FOR LACTOBACILLUS CASEI*

Casein hydrolyzate.....	0.5 gm. (dry weight)
Sodium acetate trihydrate.....	0.6 gm.
Glucose.....	1.0 gm.
Asparagine.....	25.0 mg.
Tryptophane.....	10.0 mg.
Cystine.....	10.0 mg.
Salt solution A.....	0.5 ml.
Salt solution B.....	0.5 ml.
Guanine hydrochloride.....	500.0 μ g.
Adenine sulfate.....	500.0 μ g.
Xanthine.....	500.0 μ g.
Uracil.....	500.0 μ g.
Thiamine hydrochloride.....	10.0 μ g.
Biotin (free acid).....	0.5 μ g.
Folic acid concentrate (50% folic acid).....	1.0 μ g.
Riboflavin.....	20.0 μ g.
Calcium pantothenate.....	20.0 μ g.
Nicotinic acid.....	20.0 μ g.
Pyridoxine.....	40.0 μ g.
Distilled water to.....	100.0 ml.
pH adjusted to 6.8	

Salt Solution A

K_2HPO_4	5.0 gm.
KH_2PO_4	5.0 gm.
Water.....	50.0 ml.

Salt Solution B

$MgSO_4 \cdot 7H_2O$	10.0 gm.
NaCl.....	0.5 gm.
$FeSO_4 \cdot 1H_2O$	0.5 gm.
$MnSO_4 \cdot 2H_2O$	0.337 gm.
Water.....	250.0 ml.

* For assay purposes the medium is prepared in double concentration. The above represents the concentration of the various components in the final dilution.

Medium: The composition of the complete medium is given in the above table. It is essential that all constituents be of the highest purity. Best results are obtained if the medium is prepared just before use. Stock solutions of tryptophane, cystine hydrochloride, salt solutions A and B, and purine bases may be kept on hand, using toluene as a preservative where necessary. Since the purine and pyrimidine bases are not readily soluble in water, it has been found convenient to dissolve them in the casein hydrolyzate. After the addition of riboflavin to the medium, exposure to light should be avoided.

It is necessary that great care be taken in the preparation of the casein hydrolyzate, since this is the only constituent whose composition is not chemically defined; it is, therefore, the only source of variation. Purified or "vitamin-free" casein should be reprecipitated several times in order to remove traces of interfering vitamins, particularly nicotinic acid and pyridoxine. Reprecipitation is followed by the usual acid hydrolysis, and the resulting hydrolyzate is treated with activated carbon, primarily for the removal of any biotin present. Culture medium containing casein hydrolyzate prepared in this fashion supports maximum growth of the test organism and yields satisfactory blanks for all the six vitamin assays.

Purification of Casein: To one liter of distilled water at 50°C. (122°F.) 100 grams of casein are added gradually with stirring. This mixture is stirred for 30 minutes, three grams of sodium bicarbonate (dissolved in a convenient volume of water) are added, and the stirring is continued until the casein is dissolved. It may be necessary to add more water. When solution is complete, the pH is adjusted to 4.6 with 10-per cent hydrochloric acid. The casein precipitate is allowed to settle and is removed by filtration. The reprecipitation procedure is repeated several times, depending upon the purity of the original casein. As a rule, several reprecipitations are necessary before

satisfactory blanks can be obtained in culture medium prepared with the resulting hydrolyzate.

Preparation of Casein Hydrolyzate: One hundred grams (dry weight) of the reprecipitated casein are hydrolyzed with 500 ml. of 25-per cent sulfuric acid for 10 hours at 15 pounds pressure. The sulfuric acid is neutralized with barium hydroxide and the barium sulfate is removed by filtration.

Treatment of Casein Hydrolyzate With Activated Carbon: Casein hydrolyzate solution in a concentration of 10 per cent (total solids) is acidified to pH 3 and treated with Nuchar (one gram of Nuchar to 10 grams of casein). The mixture is stirred for one hour and filtered through filter-cel. The resulting hydrolyzate may be preserved under toluene or sterilized by autoclaving. Following incubation the amount of growth is determined by titration of the acid produced, using 0.1 N sodium hydroxide. Titration may be colorimetric with bromthymol blue as the indicator, or electrometric, using either glass or quinhydrone electrode. Values obtained from the dilutions of the vitamin standard are used to construct a standard curve from which the vitamin content of any dilution of sample may be calculated. Typical standard curves for all six vitamins required by *Lactobacillus casei* were presented.

Preparation of Inoculum: Stock cultures of *Lactobacillus casei* are carried in yeast-dextrose-agar stabs and are transferred as recommended by Snell and Strong. A 24-hour culture of *Lactobacillus casei* in 10 ml. of yeast dextrose broth is centrifuged, and the bacteria are washed in 10 ml. of 0.85 per cent sodium chloride solution. The washed sediment is resuspended in four ml. of saline, and one ml. of the resulting suspension is added to 85 ml. of saline. One-tenth milliliter of this dilute suspension per tube serves as the inoculum.

Assay Procedure: For assay for any of the six vitamins, basal medium of twice the concentration given above is prepared with omission of the vitamin under test. Dilutions of the sample to be assayed are distributed into culture tubes, five ml. of basal medium added, and the final volume adjusted to 10 ml. with water. Similarly, tubes containing the basal medium with different levels of the vitamin are prepared, from which a standard curve may be established. The following are the concentrations per tube supporting maximum growth: riboflavin, 0.5 $\mu\text{g.}$; pantothenic acid, 0.4 $\mu\text{g.}$; pyridoxin, 0.8 $\mu\text{g.}$; nicotinic acid, 0.8 $\mu\text{g.}$; folic acid, 0.025 $\mu\text{g.}$; and biotin, 0.005 $\mu\text{g.}$ Several levels of the vitamin, all less than the amount required for maximum growth of the test organism, should be used in the standards. A blank containing no vitamin supplement should be included.

All tubes are sterilized for 15 minutes at 121°C.(250°F.) and cooled to room temperature. They are inoculated with a saline suspension of *Lactobacillus casei* centrifuged from a 24-hour culture grown in 10 ml. of yeast extract glucose broth, washed with 10 ml. of saline solution, and resuspended in 350 ml. of saline. One-tenth ml. of this dilution serves as the inoculum. The tubes are incubated at 37°C.(98.6°F.) for 72 hours and the growth response determined by the usual titration procedure.

CHAPTER 26

MEDIA AND THEIR PREPARATION

Bacteria are such small organisms that their environment is very important. When grown in the laboratory, they must have, among other things, the right foods.

Standard Methods and Media. All media should be prepared according to accepted formulas. In the United States, the American Public Health Association has published *Standard Methods of Water Analysis* and *Standard Methods for the Examination of Dairy Products*, in both of which methods for preparation of culture media have always been recommended.¹ The Society of American Bacteriologists also sponsors a *Manual of Methods for the Pure Culture Study of Bacteria* which includes a section on preparation of culture media. Numerous bacteriologists have shown the importance of uniform media. They have been found necessary in disinfection work, in the fermentation industries, and in examination of foods for spoilage. In some cases progress has been delayed because proper culture media were not used.

CONSTITUENTS OF MEDIA

While there are many different substances which may be used for culturing bacteria, a certain few have given such good results that they are used in many of our common media. These substances furnish as near optimum conditions as possible for the common bacteria. For those which do not grow well on ordinary media, certain pathogenic forms for instance, special media which embody the essential food substance must be prepared. Some of the pathogenic bacteria grow better if a little blood serum or hemoglobin are added. That the composition of the medium has great influence on the results obtained in bacteriology is well shown by Dawson² and others. He was able to vary such properties as the formation of enzymes, the agglutinating power, etc., by changing the composition of the medium. In some instances, it seemed as if a new strain of organism had been formed. Various factors which enter into making a good media have been studied. It should be borne in mind that the several ingredients used for making media may not be sterile.

Water Content of Constituents Used in Culture Media. The various ingredients which are used in culture media absorb water, and if comparable media are to be prepared, dry materials must be used. Agar and gelatin are especially prone to take up considerable amounts of water. Browne³ reported that agar stored in an atmosphere of 60 per cent humidity took up 20 per cent of water in nine days and 42 per cent in 25 days. Other ingredients of culture media absorbed much water in this period. Such

1. Other discussions of media and their preparation may be found in *Pure Culture Study of Bacteria*, Biotech Publications, Geneva, N. Y., Leaflet II, and in the *National Formulary*, American Pharmaceutical Assoc., Washington, D. C.

2. Dawson. 1919. *J. Bact.* 4, 133.

3. Browne. 1922. *J. Ind. Eng. Chem.* 14, 712-714.

results indicate that materials must be stored in tight containers else considerable error may be introduced into media making. The Digestive Ferments Company reported that unless shredded agar is kept in a tight container, it may contain 38 per cent of water by weight. Unless agar is kept dry, allowance must be made for water absorption.

Since colony structure and shape depend so much on the medium, Nungester⁴ devised a method for determining the hardness of agar which consisted of noticing the time required for a brass plunger .5 mm. in diameter to sink into the agar .1 mm. under a given weight. Differences in hardness of the agar were found to affect colony form of the R-S type of *Bacillus anthracis*. Such results convince one that the medium is a very important agent in the culture of bacteria.

Peptone. Commercial peptones are added to common media to supply organic nitrogen. It has been quite satisfactorily demonstrated that bacteria cannot utilize nitrogen in proteins until they have been hydrolized to simpler compounds. Consequently, bacteriologists have resorted to mixtures of the cleavage products which are distributed under the name of peptones. Important among these are the amino acids, which are hydrolyzed from protein molecules.

Many analyses of peptones are available in the literature, but as Banzhaf and Hirschleifer⁵ have pointed out, they may mean very little because in many cases the methods of analysis are not known.

Witte's peptone was formerly specified for all bacteriological media. Berry⁶ and Conn⁷ reported that equally good results are secured with the domestic peptones as with those of foreign manufacture.

Berry's conclusions were based on results secured by comparing colonies of *Eberthella typhosa*, *Escherichia coli*, and a streptococcus on agar containing two per cent of different peptones. In an extensive comparative investigation on methods of milk analysis in New York City, Conn found practically no difference in results secured with media made from three different peptone preparations. Conn considered one to be as good as another.

Chemical analyses of various peptones have been reported by a number of investigators. Myers⁸ found a variation among peptones in ability to give a test for hydrogen sulfide. Witte's brand gave better results than some domestic brands. Yaoi,⁹ in general, confirmed Myers' results. He reported that Witte's brand contained the largest amount of cystine. The buffering action of various peptones, according to Bronfenbrenner,¹⁰ may be quite different. These variations are probably of little importance in routine work. They may become very important in specialized work. Calvert,¹¹ Gage and Adams,¹² Sedgwick and Prescott,¹³ Wright,¹⁴ Tilley,¹⁵ and Wilcox¹⁶ all reported variation in results with different peptones. Treece¹⁷ stated that gas-producing substances may be present in various amounts and thus give different gas ratios. The source of the gas did not seem to be in the carbohydrate radicals. Results of analyses by McAlpine and

Brigham¹⁸ of several common American peptones did not show significant differences as far as bacterial nutrition was concerned. Reddish and Burlingame,¹⁹ however, observed that resistance of *Staphylococcus aureus* being used in disinfection work was maintained more consistently in media made with one brand of peptone. When other brands were used, resistance was reduced.

A troublesome situation in some peptones was discovered by Wright.²⁰ Peptones from which media were made were found to contain an enormous number of rod-shaped organisms which had the shape of *Bacillus mycoides*. The contamination was so heavy in the peptone under study that these cells appeared in the finished broth. Although the cells were dead they caused trouble by appearing in the films. O'Meara and Macsween²¹ have called attention to the possibility of copper in peptones interfering with bacterial development. Many bacteria failed to grow in media containing peptone and traces of copper.

Tryptone and Tryptoses. Tryptone is a peptone, devised by the Digestive Ferments Company as especially suitable for indol formation by bacteria. Since its introduction for this purpose, its usefulness has been extended to other fields. Tryptone was adopted for the standard plating medium by *Standard Methods for the Examination of Dairy Products*, 1939 edition. Tryptose is another special peptone devised for meeting growth requirements of members of the genus *Brucella*. Its use, also, has been extended to other fields. Chemical and bacteriological examination of different animal and vegetable peptones by Hook and Fabian^{21a} showed some variation in composition. Whether they are significant would be difficult to determine.

Meat Extract. This is an important constituent of laboratory media. Several brands are available in the American market. Its manufacture has been described by Bigelow and Cook.²² Formerly, Liebig's Meat Extract was specified for media. Also the extractives from the meat were prepared by soaking ground lean beef in water for 24 hours. Five hundred grams of ground lean beef were soaked in 500 ml. of distilled water in the refrigerator. At the end of this time it was filtered through cheesecloth or flannel and brought back to the original volume by adding distilled water. This meat infusion was used as the base to which the other constituents were added. Its chemical composition is not far different from that of the commercial meat extract. Gage and Adams,¹² however, have shown that the chemical composition is variable. The reaction and the organic solids are variable. This is probably due to the different grades of meat used. High amounts of fat and connective tissue will tend to give a product weaker in strength. The kind of beef might help to explain the variation in chemical content.

Gelatin. This was first used in culture media by Koch. Since that time, it has become firmly established in the bacteriological laboratory. The manufacture of gelatin has been described by Thiele,²³ who stated that all varieties, whether used for bacteriological, photographic, or food purposes,

are prepared in about the same manner. The amino acids in gelatin were studied at some length by Dakin.²⁴ Gershenfeld and Tice,²⁵ after a study of various gelatins on the market, recommended pork-skin gelatin as best for bacteriological work.

Agar-Agar. This substance has played a great role in bacteriology. Hitchens and Leiking²⁶ stated that Frau Hesse, in Saxony, introduced the substance during the late 1880's. Koch later recognized its value and adopted it in his own laboratory. This substance, according to Whittaker,²⁷ is derived from many plants but principally from those of the genus *Gelidium*, which grow on rocks along the sea coast. It is carefully cleaned by heating and washing and finally dissolved and filtered, after which it is dried in various shapes. Fellers²⁸ found a remarkable uniformity upon analysis of 16 agars from various sources.

Chemically agar is a carbohydrate, a hexosan of the cellulose group of the polysaccharides. It is not utilized by many bacteria, differing in this manner from gelatin.

Commercial shredded agar should be thoroughly washed before it is used in bacteriological culture media. Ayers²⁹ reported that large amounts of calcium and magnesium inhibited bacteria. These salts should, therefore, be removed from the agar.

It is known that the agar medium has some influence on the colonies of microorganisms which develop on it. One may wonder to what extent the work on microbial dissociation and similar topics has been influenced by the media used. According to Thomson and Thomson,³⁰ various agars have different strength and toughness. They might, therefore, give media with significantly different properties.

In recent years, dehydrated synthetic culture media have appeared on the market in large quantities. Levine³¹ reported that it was uneconomical to prepare small batches of agar media from their constituents when dehydrated products were available. Dehydrated products make it easier to prepare media of uniform composition.

At the base of agar slants, a fluid is often seen which was formerly considered to be water by many bacteriologists. However, Pijper³² maintained that this was a dilute solution of agar medium and stated that it would be more accurate to call it agar serum, and that it is merely the product of secretion caused by syneresis. When microorganisms are planted on the surface of an agar slant, they are bathed with this agar serum and thereby secure their food. Agar media, therefore, are not solid or liquefiable solid media. Hitchins³³ has suggested the use of media containing small amounts of agar. The use of such media is said to favor

the growth of some bacteria which are otherwise studied with difficulty. Hitchins pointed out the usefulness of such media in the culturing of anaerobic bacteria. In media containing .1 per cent of agar there are varying oxygen tensions possible. At the top of the medium aerobic conditions are available, since the low amount of agar cannot fill completely the volume of liquid. Below this, anaerobic conditions which prevent the ingress of oxygen are created by the agar. Healy³⁴ also reported that the liquid often found at the bottom of agar slants is not water but an exudate from the agar gel. This contains food substances and, in some cases, produces better growth of the bacteria than the agar surface itself. Besides the food substances which it contains, it probably exerts a physical influence in delaying evaporation during incubation.

REACTION OF MEDIA

Most bacteria have optimum acidities at which they develop. Consequently, it is necessary to adjust media to certain acidities when they are being studied. The desired pH is indicated for each special medium when it is quite removed from the neutral point. Methods for determining pH are many and are treated in many different books. Bacteriologists who wish information in considerable detail may consult *Pure Culture Study of Bacteria*, Leaflet IX, Biotech. Publications, Geneva, N. Y.

Colorimetric Estimation of Hydrogen-Ion Concentration. A person usually has some idea of the range of hydrogen-ion concentration of the substance which he is studying. If he is adjusting the reaction of a bacteriological culture medium, prepared according to standard methods, he will know that it will probably be about pH 6.6 to 6.8. If he desire to adjust the reaction to pH 7.0 he knows brom-thymol-blue will have to be used since its pH range is 6.0 to 7.6. Very often, however, he will not know the reaction and must, therefore, make a rough test to get the range.

Rough Test. The directions prepared by Dr. Taylor of the Lamotte Chemical Company may be followed. To make the test, fill a graduated test tube to the mark (10 ml.) with the solution to be tested and add .5 ml. of brom-thymol-blue solution. The range of this indicator is pH 6.0 to 7.6, and covers the neutral point pH 7.0. The use of the indicator will tell whether the solution is neutral, acid, or alkaline. Brom-thymol-blue is yellow at 6.0 and a deep blue at 7.6. If a color is secured which lies between yellow and deep blue the reaction is between 6.0 and 7.6. If the latter, no further rough tests are necessary. If, however, a yellow color had been obtained on addition of brom-thymol-blue, the pH would have been 6.0 or lower. Then another tube should be filled to the mark (10 ml.) with the unknown solution and .5 ml. of brom-cresol-green added since this indicator has a range of pH 4.0 to 5.6. This indicator is yellow at pH 4.0 and a deep blue at pH 5.6. If the color is between yellow and deep blue the pH is between 4.0 and 5.6. It will be noticed that in the illustrations just taken the range from 5.6 to 6.0 was not covered. For this range we have chlor-phenol-red with a range of 5.2 to 6.8. The above technic may be repeated with any of the indicators. As soon as the proper indicator is found, more delicate and accurate observations may be made.

Accurate Measurements. Having used the rough test for securing the range, let us assume that brom-thymol-blue indicator was found to be the proper one and that we now wish to know just where the reaction of the unknown substance falls between 6.0 and 7.6. For this purpose a set of color standards and a comparator are required. A set of such standards consists of nine standard tubes and one tube of distilled water. These tubes will have definite pH values of 6.0, 6.2, 6.4, and so on up to 7.6, to each of which .5 ml. of brom-thymol-blue has been added. These tubes are made in exactly

³⁴ Healy. 1926. J. Bact. 12, 179.

the same manner as are those with the unknown solution except that the pH of each tube is known. Having these standards the analyst must now simply match the tube with the unknown material with the standards. Attention must be called to the fact that an error may be introduced by matching against the color standards at either end of a given set. For instance, a test sample may match the brom-thymol-blue pH 7.6 tube and yet have a much higher pH value, owing to the fact that pH 7.6 is the end of the range for this indicator.

Adjustment of Reaction of Culture Media. Place eight ml. of distilled water in a graduated test tube (10 ml.) and add two ml. of the agar or broth to be tested. Add .5 ml. of brom-thymol-blue. The desired color is green with a yellowish tint. It may be compared, however, with the standard tube with a pH of 6.6. If it is not at this pH, dilute NaOH should be added from a burette until the desired color is secured. Multiply the number of milliliters of dilute NaOH required to bring the two ml. of medium to the proper reaction by 500 to find out how much should be added to adjust one liter of medium.

Sterilization of Culture Media. Culture media are generally sterilized in the autoclave. The high temperature and pressure have been said to induce changes in some of the constituents which cause anomalous results. Hasseltine,³⁵ for instance, compared standard lactose broth compounded before sterilization with the same basic medium to which lactose was added after tubing and sterilization. Greater amounts of gas were formed in the standard medium. Hasseltine believed this was due to hydrolysis of lactose during sterilization. Mudge³⁶ reached opposite conclusions with lactose and maltose. He stated that heating these sugars in free-flowing steam for three consecutive days caused more hydrolysis than heating in the autoclave at 15 pounds for 15 minutes. However, he advised sterilization of sugar solutions by filtration. Wolff³⁷ did not believe that the alterations in the media were significant. However, he was cautious enough to state that organisms more delicate than those he used might give different results. McAlpine³⁸ confirmed Mudge's results.

The factors involved in sterilization of culture media are quite like those involved in all methods of high-pressure steam sterilization. Cannerymen, for instance, have learned much about such things as loading the retort and rate of heat penetration into containers. Little work on the latter has been done by bacteriologists. The cannerymen have learned that success in processings cans of food depends on careful consideration of factors which may cause difficulty in sterilization. Benton and Leighton³⁹ determined the actual temperatures which were attained by media during autoclave sterilization. Large flasks of media took 15 minutes to reach autoclave temperature, 120°C.(248°F.). Culture tubes of media at the center of tightly packed baskets took 10 minutes longer to reach autoclave temperature than those at the outside of the basket. Barkworth⁴⁰ came to similar conclusions.

40. Barkworth. 1931. Centbl. Bakt., Pt. 2, 84, 353-357.

Standard Methods of Water Analysis, Eighth Edition, prescribes sterilization of all culture media in the autoclave at 15 pounds (120°C.) for 15 minutes after the pressure has reached 15 pounds. All air is to be forced from the autoclave by allowing live steam to stream through it for a few minutes before the pressure is allowed to rise. *Standard Methods for the Examination of Dairy Products* prescribes 20 minutes at the above temperatures. In addition the autoclave is to be equipped with both a thermometer and pressure gage. Whether these recommendations are adequate would be determined by the methods of packing the media in the autoclave.

Great care must be used in sterilization of media in laboratories in which *Clostridium botulinum* and thermophilic bacteria are being studied. These bacteria form very heat-resistant spores which easily survive ordinary methods of sterilization.

Effect of Sterilization on Reaction of Culture Media. Bacteriologists usually adjust the reaction of culture media before sterilization and assume that it has not been changed. It is known that changes occur in the autoclave which may not be significant in routine work but which should not be overlooked in more careful research. An alkaline medium containing glucose or lactose is rarely the same after sterilization. The best way to avoid these changes is to sterilize sugar solutions separately and add them aseptically to the sterile peptone base when the medium is needed.

Sterile sugar solutions will keep for a long time. Henry and Marshall ⁴¹ stored 20-per cent solutions of several sugars at 5°C. (41°F.) for 20 months successfully. Grace and Highberger ⁴² reported that the reaction of culture media could change during storage, a fact that should not be overlooked. Evidence on this subject is both good and sufficient. Hesse ⁴³ noted an increase in titratable acidity after sterilization. Deeleman, ⁴⁴ in order to make up for the changes in the reaction caused by sterilization, corrected the reaction by adding sterile acid or alkali after sterilization. Dernby ⁴⁵ found that sterilization of bouillon caused the pH to be raised. He explained this on the basis that carbon dioxide was driven off from bicarbonates, thus increasing the concentration of carbonates and making the media more alkaline.

According to Mudge, the acidity produced during sterilization is due to a reaction between sugar and amino groups. Clark ⁴⁶ explained the changes as due to oxidation of sugar as well as to greater solution of glass at higher temperatures. That the sugars are altered by sterilization was suggested by Dernby and Allander. ⁴⁷ They found that when sugar was present in bouillon, acid was formed during sterilization. When no sugar was present, the hydrogen-ion concentration was slightly higher after autoclaving but later returned to its original value. Similar observations

were recorded by Foster and Randall.⁴⁸ Smith⁴⁹ reported hydrolysis of maltose by heating in the autoclave. Autoclaving sugar solutions for 30 minutes at 120°C.(248°F.) was much more destructive than "momentary heating," according to Davis and Rogers⁵⁰; it was found to be only slightly more restructive than the usual intermittent method. They did not consider heating the sugar apart from the medium to be necessary. Differences in results of fermentation tests carried out with both types of media were not significant. Momentary autoclaving of all sugar broths at pH 6.6 was recommended. Another effect of autoclaving sugar media, observed by Baumgartner,⁵¹ is formation of substances which increase the rate of destruction by heat of microorganisms.

Sterilization by autoclaving at 112°C.(233.6°F.) for 15 minutes or steaming for 30 minutes on three successive days, of reducing sugars dissolved in McIlvaine's buffer or nutrient broth results in the formation of material which increases the rate of thermal destruction when *Escherichia coli*, suspended in such solutions, is heated at 54°C.(129.2°F.). In autoclaved glucose-broth at 37°C.(98.6°F.) growth of *Escherichia coli* was slightly inferior to that in filtered sterilized media. These effects appear to be due to the direct toxic action of material formed during heat sterilization. Production of toxic material is increased by increasing the heat treatment of the solutions; it is formed concurrently with caramel. For its production in distilled water solution, the heat treatment must be sufficient to cause caramelization. The toxic material is not produced when reducing sugar solutions are sterilized by filtration. Filter-sterilized glucose, galactose, lactose, maltose, sucrose, mannitol, and glycerol in .5 M concentrations in buffer or broth were all found to decrease the rate of thermal destruction of *Escherichia coli*. A preliminary chemical investigation failed to reveal the nature of the toxic material. Advantages of media which have not been heated have been mentioned frequently. Schweizer⁵² described apparatus and procedures for accomplishing cold sterilization.

When working with heat-resistant bacteria it is necessary to give special attention to sterilization of apparatus and media. *Clostridium botulinum* and some of the thermophilic bacteria causing spoilage of canned foods are in this category.

Sugar-Free Media. Sugar-free media are necessary in careful fermentation work. Smith⁵³ observed that muscle sugar might reach as high as .3 per cent. Such sugar must be eliminated.

The commonest and perhaps most useful method for accomplishing this is to inoculate the medium with a pure culture of *Escherichia coli* and incubate overnight. Randall and Hall⁵⁴ advised the use of *Clostridium welchii*. It seemed to give more complete decomposition of sugar, since gas

formation went on after the commonly used organisms, such as *Escherichia coli*, had ceased growing.

BOUILLON MEDIA

Such media form the base from which many others are made. Cook and LeFevre⁵⁴ studied bacteriological bouillons to determine how much variation occurred when they were prepared according to standard procedures. They found that beef bouillons were fairly constant in composition, but contained more creatin and creatinin than the meat extract or liver bouillons. The liver bouillons showed greatest variation. Comparisons of "infusion" media and "meat extract" media showed more nutrient material in the "infusion" media. From their results it seems advisable to add peptone to the coagulated meat juice, and not before this coagulation.

Nutrient broths or plain bouillons are usually made from water, peptone, and meat extractives. The extractives are secured either in commercial meat extract or by soaking fresh meat in water.

Nutrient Broth (Standard Methods for the Examination of Water and Sewage).

1. Add three grams of meat extract and five grams of peptone to a liter of distilled water.
2. Heat slowly on the steam bath to at least 65°C. (149°F.).
3. Adjust reaction so that the pH after sterilization will be between 6.4 and 7.0.
4. Bring to a boil, cool to 25°C. (77°F.), and filter through paper until clear.
5. Distribute in test tubes, about 10 ml. in each tube.
6. Sterilize in the autoclave at 15 lb. pressure (120°C. or 248°F.) for 15 minutes after the pressure reaches 15 lb.

A concentrated nutrient bouillon was suggested by Moon.⁵⁶ The ingredients for 10 liters were added to one liter of water and stored after autoclaving. Moon stated that an exceedingly clear medium was secured and that considerable titrating and filtering were eliminated. By this procedure one would not avoid changes in reaction owing to reheating for sterilization.

Standard Nutrient Broth, Standard Methods for the Examination of Dairy Products, 1941 Edition. The medium is compounded as follows:

Tryptone, Bacto.....	1,000 ml.
Beef extract.....	5 gm.
Distilled water.....	3 gm.

Coconut-Milk Medium. Blauvelt⁵⁷ recommended use of unsterilized coconut milk as a culture medium. The fluid is drawn aseptically from ripe coconuts with a sterile syringe and added to either plain broth or plain agar in concentrations of 10 to 25 per cent. Growth of microorganisms was said to be about doubled on this medium.

Brewer's⁵⁸ Thioglycollate Medium for Cultivating Anaerobic Bacteria. This medium was devised to provide a clear culture medium for anaerobic bacteria. Glucose infusion broth containing .05 per cent of agar is the base. To this is added .1 per cent of thioglycollate to provide proper oxidation-reduction potential. The practical value of this medium rests mainly in the fact that no effort need be made to make the medium anaerobic. An E_h indicator may be employed to give color to any portion of the medium when it becomes aerated. Although other media have been used successfully for the "aerobic" cultivation of anaerobes, this is the first clear liquid medium which will remain anaerobic for a long time without the aid of a seal or of special apparatus. For example, tubes of this medium which were stored for a month at room temperature

55. Cook and LeFevre. 1918. Amer. J. Pub. Health 8, 587-589.

56. Moon. 1927. Idem 17, 640.

57. Blauvelt. 1939. J. Lab. and Clin. Med. 24, 420-423.

58. Brewer. 1940. Amer. Med. Assoc. J. 115, 598-600; J. Bact. 39 (1940), 10.

and then inoculated (test-organisms: *Clostridium novyi*, *Clostridium tetani*, *Clostridium septicum*, *Clostridium botulinum*, *Clostridium histolyticum*, *Clostridium welchii*, *Clostridium sporogenes*, and several strains of anaerobic streptococci) gave growth equivalent to that obtainable in control cultures in "anaerobe" jars. A comparative study of this medium with other media employed for the cultivation of anaerobes was made.

A sugar-free base medium for fermentation reactions, a modification of the above medium, was proposed by Reed and Orr.⁵⁹ It contained:

Bactopeptone or proteose peptone.....	20.0 gm.
Sodium chloride.....	5.0 gm.
Sodium thioglycollate.....	1.0 gm.
Agar.....	1.0 gm.
Water.....	1,000.0 ml.

Sugars in amounts of one per cent are added to the base before tubing and sterilization.

Mickle and Breed's⁶⁰ Tomato-Juice Broth. This medium was found to be useful for isolation and growth of tomato products spoilage bacteria.

Nutrient broth.....	900 ml.
Tomato juice or tomato pulp.....	100 ml.
Reaction pH 6.8 to 7.2	

Place the material in Durham fermentation tubes. Sterilize under 10 lb. pressure for 15 minutes, or fractionally in an Arnold sterilizer for 30 minutes on three successive days. Incubate between 20 and 41°C. (68 and 105.8°F.). (Room temperature is satisfactory.)

A solid tomato-juice agar was made by adding 10 per cent of tomato juice to ordinary nutrient agar just before sterilization.

Pederson's⁶¹ Yeast-Water Tomato Juice. This medium was used for determining the types of spoilage bacteria in tomato products. A clear yellow tomato juice was prepared by boiling, macerating, and filtering tomatoes through cheesecloth. The medium had the following composition:

Yeast water.....	900 ml.
Filtered tomato juice.....	100 ml.
Reaction pH 6.6 to 6.8	

Autoclave at 15 lb. pressure for five hours a 10-per cent suspension of starch-free yeast. Allow to settle in the refrigerator several days. When clear, decant the supernatant liquid.

Place in Durham fermentation tubes and sterilize in the autoclave at 10 lb. pressure for 15 minutes, or fractionally in an Arnold sterilizer. For a plating medium dissolve 1.5 per cent agar in the yeast water and add the tomato juice just before sterilization.

Liver-Broth Medium for Detection of Thermophilic Bacteria Not Producing Hydrogen Sulfide in Canned Foods.⁶² This medium is used for detecting presence of *Clostridium thermosaccharolyticum* and other putrefactive and mesophilic anaerobic bacteria. Mix chopped beef liver with water in proportion of 500 gm. to 1,000 ml. Boil the mixture slowly for one hour, adjust to about pH 7.0, and boil for an additional 10 minutes. Then press the boiled material through cheese cloth and make liquid to 1,000 ml. Add 10 gm. of peptone and one gm. of dipotassium phosphate to the broth. In tubing introduce from one-half to one inch of previously boiled ground beef liver into the tube.

Before using, unless it is freshly prepared, exhaust the medium by subjecting to streaming steam for at least 20 minutes, and after inoculation, stratify it with a

60. Mickle and Breed. 1925. N. Y. Agr. Expt. Sta. Tech. Bull. 110.

61. Pederson. 1929. N. Y. Agr. Expt. Sta. Tech. Bull. 150.

62. Official and Tentative Methods of Analysis, Assoc. Off. Agr. Chem., fifth edition, p. 642.

two to two and one-half inch layer of plain nutrient agar which has been cooled to 50°C.(122°F.).

Linden's⁶³ Medium for Yeasts and Molds. While this medium has been especially recommended for yeasts in tomato products, it is probably satisfactory for examination of other foods for these fungi.

Tryptic milk digest.....	100 ml.
Bacto yeast extract.....	2 gm.
Tomato juice.....	100 ml.
Dextrose.....	10 gm.
Distilled water to make.....	1,000 ml.

Prepare the tryptic milk as follows: To a liter of skim milk, add sufficient anhydrous sodium carbonate to adjust the reaction to pH 8. Add a paste consisting of two grams of Fairchild's trypsin, or two ml. of freshly prepared enzyme. Add 25 ml. of chloroform and incubate at 30°C.(86°F.) for 24 to 48 hours. Agitate at intervals and maintain the optimum pH. After digestion neutralize with 10 per cent hydrochloric acid, and heat in a double boiler or on a water bath to remove the chloroform. Sterilize 100-ml. aliquots in the autoclave for 15 minutes at 15 lb. pressure.

Place in fermentation tubes, or medium-sized test tubes, and sterilize in the autoclave for 15 minutes at 15 lb. pressure or fractionally. Before using, heat the tubed medium in boiling water 10 minutes, cool, and inoculate. When fermentation tubes are not available, overlay the tubed broth with vaspar seal. For a plating medium, add 15 grams of agar and dissolve by boiling, or heating, in an Arnold sterilizer, adding the tomato juice before sterilization.

Carbohydrate Broths. These are usually made by adding one per cent of the carbohydrate to plain broth. With media prepared from meat infusion to be used in research work, or where very accurate results are desired, it may be necessary to remove the muscle sugar. With ordinary media made with meat extract this is probably not necessary. Careful attention, however, must be given to the carbohydrates. Masucci and Ewe⁶⁴ have stated that sugars for bacteriological media should be carefully selected and stored in tight containers, since they are quite hygroscopic.

Nutrose Medium (Purwin and McNutt⁶⁵). Nutrose in one-per cent solution was substituted for sugar-free broth and peptone in the preparation of carbohydrate media. This gave good results with 172 strains of 20 different organisms. The medium had the following composition:

Nutrose.....	1.0 part
Water.....	90.0 parts
Sodium chloride.....	0.5 parts

Mix and allow to stand overnight. Adjust reaction to pH 7.7. The mixture should be steamed in the Arnold for two hours and filtered through cotton. Add one per cent of Andrade's indicator.

Stickel and Meyer's⁶⁶ Peptic Digest Media. Stickel and Meyer devised a number of inexpensive media for bacteriological work. These media were later used by Meyer in his work on botulism.

I. PREPARATION OF PEPTIC DIGEST BROTH OF LIVER, BEEF OR HUMAN PLACENTA

Preparation of Stock Digest Broth. 1. Wash clean, and mince finely five or more large pigs' stomachs. Mince an equal amount of clean pig or beef liver, cheap fat-free beef, placenta, or blood clots.

63. Linden. 1936. Assoc. Off. Agr. Chem. J. 19, 445; 21 (1938), 454-457.
64. Masucci and Ewe. 1920. J. Lab. and Clin. Med. 5, 609-612.
65. Purwin and McNutt. 1924. Abs. Bact. 8, 1695.
66. Stickel and Meyer. 1918. J. Infect. Dis. 23, 68-81.

2. Mix in the following proportions:

Minced stomachs.....	400 gm.
Minced liver, beef, or placenta.....	400 gm.
Hydrochloric acid (Baker Chemical Co.).....	40 gm.
Tap water at 50°C.(122°F.).....	4,000 gm.

Keep the mixture at 50°C.(122°F.) for 18 to 24 hours.¹

3. Make a biuret and also a tryptophane test.² When both reactions are positive, the digest has a yellowish-greenish color and contains very little undigested debris.

4. Transfer to large bottles³ and steam for 10 minutes at 100°C.(212°F.) to stop digestion. Strain the digest through cotton, or preferably store overnight in the refrigerator and decant after 24 hours.

5. Warm the filtrate or decanted digest to 70°C.(158°F.) and neutralize with sodium carbonate (twice normal solution) to litmus at this temperature.

6. Sterilize⁴ (if not to be used at once) in the autoclave at 10 lb. pressure for 15 minutes, or for 30 minutes at 100°C.(212°F.) on two successive days and store away.

This stock digest is used for the various media as follows:

(a) *Plain Digest-Broth*. 1. Filter the desired amount into a flask.

2. Add .2 per cent dibasic potassium phosphate (K_2HPO_4).

3. Set the desired reaction by using litmus, or, preferably, to a definite H-ion concentration (pH 7.0 to 7.5) by one of the reliable methods recommended for the determination of the H-ion concentration. (Hurwitz, Meyer, Ostenberg, Clark, and Lubs or Cole and Onslow.)

4. Heat the broth in the steamer at 100°C.(212°F.) for 15 minutes.

5. Correct the reaction and filter through paper.

6. Distribute in the receptacles used for cultures and sterilize at 100°C.(212°F.) according to the usual routine method.

(b) *Sugar-Free Digest-Broth*. 1. Inoculate the sterile "stock" digest in a flask or bottle with one per cent of a 24-hour-old broth culture of *Bacillus saccharolyte* or *Escherichia coli* and incubate for 12 to 18 hours at 37°C.(98.6°F.).

2. Steam for 20 minutes.

3. Adjust the reaction and add .2 to .4 per cent dibasic potassium phosphate and two per cent purified talcum. Filter through paper, distribute for use, sterilize; or use the turbid, killed saccharolyte culture (without previous cleaning) for the preparation of agar. Note method given under "c."

(c) *Stock Digest Agar*. 1. Take a measured quantity (8 to 10 liters) of stock digest; add .2 per cent dibasic potassium phosphate (K_2HPO_4), and two per cent of agar⁵ fiber.

2. Autoclave at 10 lb. pressure for three-quarters of an hour or heat in a double-boiler to 100°C. and keep the mixture at this temperature until the agar is dissolved.

3. Restore the volume lost by evaporation.

4. Set the reaction very lightly alkaline to litmus or to pH 7.3 by using twice normal NaOH or KOH. Special attention should be given to the adjustment of the reaction, because some commercial agar fiber hydrolyzes readily in the presence of acid.

¹ It is advisable to digest the mixture in glass or porcelain receptacles. They have been accustomed to placing museum jars with the digest in a large, electrically regulated water-bath. Very good results, however, have also been obtained by using a large enameled pot equipped with a "Therm-Elect" thermo-regulator and heating unit installed by the Electric Sales Service Company of San Francisco.

² To five ml. of filtered digest add .1 ml. of five per cent solution of copper sulphate; mix and then add five ml. normal sodium hydroxide. Pink color indicates complete peptonization.

To 10 ml. of neutralized and filtered digest add, slowly, bromine water until the maximum purple coloration is reached.

³ The bottles in which the Baker Chemical Company supplies hydrochloric or sulfuric acid are excellent for this purpose.

⁴ Overheating by long continued sterilization should be avoided, the medium becoming dark brown and losing considerable of its nutritive value.

⁵ The inexpensive agar fiber of the present market varies considerably in quality and contains from 10 to 15 per cent water. Some lots of agar will be improved by previous treatment with glacial acetic acid (.2 to .3 per cent) and subsequent thorough washing.

5. Cool to 60°C.(140°F.) and add the white of an egg, beaten with the crushed shells (or, for the sake of economy, ordinary beef or sheep serum in the quantity of 25 to 50 ml. per liter).

6. Autoclave for one hour at 115°C.(239°F.).

7. Filter through cotton and distribute in bottles of 200 to 500 ml. quantities.

8. Sterilize in the customary manner.

(d) *Trypsinized Digest Broth*. 1. Peptic digest prepared up to Stage 4 of the general outlines is not strained or placed in the refrigerator, but is cooled at 80°C. (176°F.) and made faintly alkaline to litmus with twice normal KOH or twice normal sodium carbonate.

2. Cool to 37°C.(98.6°F.) and add one per cent pancreatic extract (prepared according to the methods given in Plimmer's Practical Organic and Biochemistry, London, 1915, p. 405, or in the paper of Cole and Onslow, *Lancet*, 1916, 2, p. 10) or "Bacto" trypsin (marketed in sterile ampoules by the Digestive Ferments Company, Detroit).

3. Keep the mixture at 37°C.(98.6°F.) for three to 10 hours depending on the action of the trypsin and the digestion desired. Control the process by repeated tests for tryptophane.

4. When trypsinizing is sufficiently advanced, render slightly acid with glacial acetic acid and bring slowly to boiling point for 10 minutes.

5. Filter through paper, or keep in cool place overnight and decant the clear liquid in the morning.

6. Add .2 per cent dibasic phosphate, adjust the reaction to faintly alkaline or to the desired H-ion concentration, and treat in the manner outlined in Section "a," or use for the preparation of agar.

(e) *Sugar-Free Trypsinized Digest Broth*. This can be prepared by the following modification of the method given in Section "d."

1. At Stage 2 of the process, add simultaneously with the pancreatic extract or trypsin solution .2 per cent of dibasic potassium phosphate, one per cent calcium carbonate, and one per cent of a 24-hour-old broth culture of *Bacillus saccharolyte*.

2. Incubate at 37°C.(98.6°F.) for 12 to 18 hours and control the digestion by tryptophane tests and removal of carbohydrates by the gas formation in fermentation tubes.

3. When the digest is sugar-free, steam for 15 minutes and use for the preparation of agar; or

4. Set to the desired reaction and steam for another 15 minutes.

5. Filter through paper; the calcium carbonate present will assist materially in obtaining a perfectly clear filtrate.

6. Distribute and sterilize in the usual manner.

II. PREPARATION OF TRYPTIC DIGEST BROTH OF HUMAN PLACENTA OR BEEF HEART

1. Prepare some fresh beef hearts by removing the fat and vessels, mince finely, and weigh. Fresh, human placentas are rinsed in water * and also passed through a meat chopper.

2. To 500 gm. of the minced beef hearts or human placentas, add 1,000 gm. of tap water. Make faintly alkaline to litmus with normal KOH or Na₂CO₃, and heat slowly to 70 to 80°C. for 5 to 10 minutes.

3. Cool to 37°C. and add one per cent pancreatic extract or "Bacto" trypsin (details are given under Heading 1, Section "d"), and keep at 37°C.(98.6°F.) for two to five hours. Control the progress of digestion by repeated biuret and tryptophane tests. In case the digestion is extended over a period of six hours, it is necessary to add chloroform or toluene.

4. When the process is sufficiently advanced, render slightly acid with glacial acetic acid and boil slowly for 15 minutes.

5. Either filter or decant the clear fluid which results on placing the digest overnight in a cool place.

6. Adjust the reaction, add .2 per cent dibasic potassium phosphate, and, if necessary, add the minerals (chloride of magnesium, sodium, etc.), in which the broth is deficient for reasons.*

7. Heat for 15 to 30 minutes in the steamer at 100°C.(212°F.) and filter again, if necessary.

8. Sterilize at 100°C.(212°F.) on three consecutive days, if not to be used at once.

III. PEPTIC AND TRYPTIC DIGESTS OF WHOLE BLOOD OR BLOOD CLOTS

(a) *Peptic Digests*. 1. Obtain from the abattoirs in clean containers 10 liters of fresh beef blood. Decant and store the serum which has separated on standing in a refrigerator from 12 to 18 hours).

2. Weigh the blood clots and mix each 100 gm. with one liter of tap water.

3. Place the mixture in an enameled pot, bring slowly to a boil, and under constant stirring keep it at this temperature for five minutes.

4. Cool to 50°C., add to each liter of the mixture 100 gm. of mixed pigs' stomach (for preparation, see the instructions given in the appendix under Method 1), transfer to glass or porcelain receptacle, and finally add one per cent hydrochloric acid.

5. Digest at 50°C.(122°F.) for 18 to 24 hours and treat the resulting digest as outlined in Method 1. (Steps 3 to 6, and Section "a," Steps 1 to 3.)

6. Clear the neutralized broth or agar by adding five to 10 per cent of the decanted beef serum, steam for 45 to 60 minutes.

7. Remove the flasks or bottles from the steamer and allow the clot to form a compact mass; decant or, better, centrifuge the medium to remove it.

8. Sterilize at 100°C.(212°F.) as customary.

(b) *Tryptic Digests*. 1. The preparation of the blood substratum for digestion is practically identical, as given under Section "a," Stages 1 to 4. Use, however, 500 gm. of blood clot to one liter of tap water.

2. Strain the fluid portion of the mixture through cheesecloth and pass the residue through a fruit press. Cool to 37°C.(98.6°F.).

3. Make the thick, brownish fluid slightly alkaline to litmus, add one per cent pancreatic extract and keep at 37°C. for five to 24 to 48 hours.

4. The further treatment of the digest is the same as given under Heading II, Stages 4 to 8.

5. The neutralized broth or agar can be cleared with decanted serum, the resulting medium is excellent for primary isolation of highly parasitic organisms.

Dubovsky and Meyer's⁶⁷ Beef Heart-Peptic Digest Broth. This medium was said to be especially suitable for formation of toxin by *Clostridium botulinum*. The authors outlined its preparation as follows:

(1) Slowly heat to boiling finely ground, fat-free heart, 1,000 gm., and tap water, 1,000 ml.; adjust to a reaction of pH 8.0 to 8.2. Then cool and carefully skim off the layer of fat which floats on the cold medium. To each liter of beef-heart mash, add two liters of peptic digest broth, see (2). Adjust the reaction to pH 7.2 to 7.4.

(2) Wash clean and mince finely five or more large pigs' stomachs. Mince an equal amount of clean pig or beef liver. Mix in the following proportions: minced pig stomachs, 400 gm.; minced liver, 400 gm.; hydrochloric acid (Baker Chemical Co.), 40 gm.; and tap water at 50°C., 4,000 gm.

Keep the mixture in glass or porcelain receptacles for 18 to 24 hours. Make biuret and also tryptophane tests. When both reactions are positive, the digest is green-yellowish and contains little undigested debris. Transfer to large bottles and steam for 10 minutes at 100°C. to stop digestion. Strain the digest through cotton or preferably store overnight in the refrigerator and decant after 24 hours. Warm the decanted digest to 70°C. and neutralize with sodium carbonate (twice normal solution) to litmus at this temperature. Filter the desired amount, add .2 per cent of dipotassium phos-

* In case distilled water is used or the tap water is poor in calcium and other minerals, calcium, sodium, and magnesium chloride, as well as phosphate, have to be added. The following amounts have proven satisfactory: sodium chloride .5 per cent; calcium chloride .01 per cent; magnesium sulphate .02 per cent, and dibasic calcium phosphate .2 per cent.

67. Dubovsky and Meyer. 1922. J. Infect. Dis. 31, 501-540.

phate; adjust to pH 7.4, and mix with beef heart mash. Adjust the final reaction and sterilize for one hour at 18 lb. of pressure. Incubate for five days and repeat the same sterilization for one hour at 18 lb. of pressure.

Before inoculation, "exhaust" in the manner suggested for the liver-broth medium. After inoculation, stratify with sterile vaseline.

For general use, this medium carries the obvious disadvantage that it is difficult to prepare. Where any intensive study of putrefactive spoilage is made, however, it is regarded as a valuable medium.

Darby and Mallmann's⁶⁸ Medium for Coliform Bacteria. The following medium was developed as an enrichment medium for coliform bacteria in sanitary work. Bacto-tryptose was found to be superior to Bacto-peptone in the base medium.

Bacto-tryptose.....	2.0	per cent
Lactose.....	0.5	per cent
K ₂ HPO ₄	0.4	per cent
KH ₂ PO ₄	0.15	per cent
NaCl.....	0.5	per cent
Water.....	1.0	liter

This medium was especially devised for water analysis.

Tryptone Broth—Standard Methods of Water Analysis, A.P.H. Assoc., Eighth Edition, Test for Indol. Add 10 grams of Bacto-tryptone to 1,000 ml. of distilled water and heat with stirring to obtain complete solution.

MacConkey's Broth (Single Strength). This medium has had an important place in sanitary work in Great Britain. Its preparation is described on page 372 of this book.

Bailey's⁶⁹ Modified "Hormone" Gelatin Broth. Select a good gelatin, weigh out 10 gm. and dissolve it in a liter of distilled water, then proceed exactly as in the method described for preparation of the agar medium as described below. Bailey⁶⁹ claimed that this medium was especially valuable for preserving cultures of organisms like the penumococcus which die out quite rapidly on laboratory media.

Jackson and Muer's⁷⁰ Liver Broth:

Beef liver.....	500 gm.
Peptone (Witte's).....	10 gm.
Dextrose.....	10 gm.
Potassium phosphate.....	1 gm.
Water.....	1,000 gm.

1. Chop 500 gm. of beef liver into small pieces and add 1,000 ml. of distilled water. Weigh the infusion and container.

2. Boil slowly for two hours in a double boiler, starting cold, and stirring it occasionally.

3. Make up the loss in weight by evaporation and strain through a wire strainer.

4. To filtrate add 10 gm. of peptone, 10 gm. of dextrose, and one gm. of potassium phosphate. Weigh the infusion and container.

5. After warming this mixture in a double boiler and stirring it for a few minutes to dissolve the ingredients, titrate with N/20 sodium hydroxide, using phenolphthalein as an indicator, and neutralize with normal sodium hydroxide.

6. Boil vigorously for 30 minutes in a double boiler, and five minutes over a free flame with constant stirring to prevent the caramelization of the dextrose.

7. Make up any loss in weight by evaporation, and filter through cotton flannel and filter paper.

8. Tube and sterilize in an autoclave for 15 minutes at 120°C.(248°F.).

Cameron, Williams, and Thompson's⁷¹ Liver Broth Medium. While this medium was devised especially for the detection of thermophilic anaerobes in canned foods and sugar, it has wider uses. Cameron described its preparation as follows:

68. Darby and Mallmann. 1939. Amer. Water Wks. Assoc. J. 31, 689-706.
69. Bailey. 1925. J. Infect. Dis. 36, 340-342.
70. Jackson and Muer. 1911. J. Infect. Dis. 8, 289-294.
71. Cameron, Williams, and Thompson. 1928. Natl. Canners Assoc. Bull. 25-L.

Five hundred grams of chopped beef liver are mixed with 1,000 ml. of water and boiled slowly for one hour, after which the boiled material is pressed through cheese-cloth and the liquid is made to 1,000 ml. To the broth are added 10 grams peptone and one gram K_2HPO_4 . The reaction is adjusted to pH 7.0. In tubing one-half inch to one inch of the previously boiled ground beef liver is introduced into the tube.

Eyre's⁷² Oyster Media. The following media were used by Eyre in the examination of oysters.

Oyster Broth. Mince the bodies of oysters to the weight of 500 grams. Extract at 37°C.(98.6°F.) for 30 minutes in 1,000 ml. of sterilized sea water. When sea water is not available use three per cent of sodium chloride. Filter, tube, and sterilize. Reaction need not be adjusted.

Oyster Agar. To oyster broth described above, add two per cent of powdered agar.

Oyster Gelatin. Add 10 per cent of gelatin to oyster broth described above.

Nitrate Broth. This is a special broth containing nitrite-free nitrate. It may be prepared in different ways. *Standard Methods for the Examination of Water and Sewage, 1912*, recommended a medium of the following composition:

Tap water.....	1,000 ml.
Witte's peptone.....	1 gm.
Potassium nitrate (nitrite free).....	0.2 gm.

Another formula is as follows:

Distilled water.....	1,000 ml.
Leibig's meat extract.....	3 gm.
Potassium nitrate c.p.	10 gm.

Breed⁷³ has shown that by increasing the peptone content of nitrate broth to five grams per liter more uniform results were obtained when 50 cultures of *Escherichia coli* were tested for nitrate reduction. With soil bacteria one per cent peptone seemed to allow more constant results. He concluded that nitrate destruction must be tested for in media which allow vigorous growth of the organisms. Suitable nitrate broths may have to be devised to fit each group.

Trypsin Broth (Gordon et al.⁷⁴). Take some fresh beef heart free from fat and vessels, mince the meat very finely, and weigh. To each one-half kilo add one liter of water and make faintly alkaline to litmus with 20 per cent KOH solution. Heat this slowly to 75°C.(167°F.) to 80°C.(176°F.) for five minutes. Cool to 37°C.(98.6°F.) and add one per cent of liquor trypticum compositum, and keep it at 37°C. for two and one-half to three hours. When trypsinizing is finished, test for peptone with copper sulfate and KOH, then render slightly acid with glacial acetic acid, and bring slowly to boil for one-quarter hour. Leave overnight in a cool place, and siphon off the clear liquid in the morning. Make faintly alkaline to litmus, and sterilize in an autoclave at 118°C.(244.4°F.) for one hour on each of two days (if not to be used at once).

Trypsin has been employed in the preparation of a number of culture media to hydrolyze some of the complex nitrogenous bodies and make them more available to the bacteria. While such media have been most generally used with pathogens, they are being used now for some non-pathogens, such as the anaerobic sporeformers.

Dextrose Potassium Phosphate Broth:

Witte's peptone.....	5 gm.
Dextrose.....	5 gm.
Di-potassium hydrogen phosphate.....	5 gm.

Heat with occasional stirring over steam for 20 minutes. Filter and cool to 20°C.(68°F.). Dilute to 1,000 ml. with distilled water. Tube and sterilize. (*Standard Methods of Water Analysis, 1917, p. 210.*)

72. Eyre. 1923. Roy. Micros. Soc. J., 385-394.

73. Breed. 1915. Science 41, 661.

74. Gordon, Hine, and Flack. 1916. Brit. Med. J., p. 678.

Tryptone Broth. To 1,000 ml. distilled water add five gm. di-potassium phosphate, .3 gm. tryptophane, and one gm. peptone. Heat until the ingredients are thoroughly dissolved, tube, and sterilize at 15 lb. for 15 minutes. Some American peptones are standardized to contain tryptophane. If such peptone is used, the tryptophane in the above formula may be omitted and the peptone increased to five gm.

Peptone Solution (Dunham):

Witte's peptone.....	10 gm.
Distilled water.....	1,000 ml.

Reaction not adjusted.

Herring Broth (Sadler ⁷⁵). In his investigations on the bacteriology of swelled canned sardines, Sadler used the following broth: Fresh herrings were washed and ground up, no part being discarded. This ground mass was mixed with the sea water to the rate of one part of herring to one-half part of sea water and heated for several hours in an autoclave or Arnold. After cooling, the fat was skimmed off and the mixture heated again. It is then strained through cheesecloth, the filtrate serving as a standard herring extract, used in the preparation of other media. Good results were obtained by Sadler with the following mixture:

Standard broth.....	1,000 ml.
Sea water.....	500 ml.
Peptone.....	15 gm.

These ingredients were heated together in an Arnold, the reaction adjusted to 1+ with phenolphthalein.

Endo's Broth or Bouillon. This medium is prepared like Endo's agar, except that agar is not added. It has been used for detecting *Escherichia coli*. According to McAuliffe and Farrell ⁷⁶ addition of one ml. of milk to fuchsin lactose broth causes such amounts of the dye to be absorbed that the medium may lose some of its selectivity in detecting coliform bacteria.

Crystal Violet Broth (Salle ⁷⁷). This medium was proposed by Salle for the presumptive test for *Escherichia coli*; the author described its preparation as follows:

Place one gram of crystal violet in a glass stoppered bottle of 150-ml. capacity and add 50 ml. of 95 per cent alcohol. Shake thoroughly and then add 50 ml. of distilled water. Shake well again, until all of the dye is dissolved. Pipette 20 ml. of this one per cent solution into a liter volumetric flask. Add sufficient water to make 1,000 ml. This gives a 1:5,000 solution of crystal violet.

The medium for the presumptive test is now prepared as follows:

Peptone, Difco.....	15.0 gm.
K ₂ HPO ₄	15.0 gm.
KH ₂ PO ₄	3.0 gm.
Lactose.....	15.0 gm.
Crystal violet (1:5,000).....	21.5 ml.
Distilled water to make the quantity = 2,000 ml.	

Mix ingredients and stir until solution is effected. Distribute the medium into test tubes, 20 ml. to each tube. Sterilize in an Arnold sterilizer or in the streaming steam of an autoclave for 10 minutes. Only one heating is necessary to sterilize. Autoclaving under pressure will decompose some of the dye, making the medium unfit for use. It is not necessary to adjust the reaction of the medium as this is controlled by the buffer salts.

The composition of this medium was determined for a sample of 10 ml. of water in 30 ml. of medium. If smaller samples are desired, an adjustment must be made in order not to alter the proportions of various constituents.

77. Salle. 1930. J. Infect. Dis. 41, 1-8.

Brilliant Green Lactose Bile (Muer and Harris⁷⁸). The following medium was found to possess a distinct selective action on *Escherichia coli* in the presumptive test in water analysis. Its preparation was given as follows:

1. Heat one liter of distilled water in a double boiler until water in the outer vessel boils.
2. Add 50 grams of dried ox gall and 10 grams of peptone, stirring until all ingredients are dissolved.
3. Continue boiling for one hour.
4. Remove from the flame and add 10 grams of powdered lactose.
5. Filter through cotton flannel until clear.
6. To each liter of the filtrate add 10 ml. of a one-per cent solution of brilliant green.
7. Tube and sterilize in autoclave for 15 minutes at 15 pounds pressure.

McAuliffe and Farrell⁷⁶ pointed out that when milk is added to such a medium as brilliant green lactose bile, so much of the dye may be absorbed that the medium will lose some of its selectivity. Kline⁷⁹ found that some lots of brilliant green were bacteriostatic and might not be satisfactory in culture media. Other materials in the medium were shown by Stark and Curtis⁸⁰ to be active in reducing the toxicity of .00133 per cent of brilliant green. This amount of brilliant green in one per cent peptone and one per cent lactose completely inhibited growth of all members of the coliform group. When two per cent of ox gall was added, growth of the *Escherichia* strains was accelerated but *Aerobacter* strains were slightly inhibited. Stark and Curtis believed that media containing an inhibitory substance are subject to error unless the affects of other substances (proteins) are understood. Further consideration of this question is given later in this chapter.

AGAR MEDIA

Agar media are frequently like liquid media except that agar is added to give a medium which is solid at room temperature. Plain agar is a basic medium to which many other materials may be added to give special media. Thomson and Thomson³⁰ stated that nutrient agar should not be overheated. Prolonged heating changes the color from a faint straw-colored tint to a deep yellow or brown. This change is apparently due to either acid or alkali hydrolysis. Prolonged heating causes a loss of jellying power. Furthermore, the deep brown substance formed by heating in the presence of alkali may be detrimental to the growth of some bacteria.

Preparation of Nutrient Agar (Standard Methods of Milk Analysis). Old Formula. The final medium is not unlike that secured by other methods. The following ingredients are used:

Agar (market, not oven dried).....	1.5 per cent
Beef extract.....	0.3 per cent
Peptone.....	0.5 per cent
Distilled water.....	1,000.0 ml.

Procedure No. 1. Mix all of the ingredients together, cold. Heat in an autoclave at 15 lb. pressure for 40 to 90 minutes according to the quantity of medium being made in each batch. Allow the autoclave to cool very slowly so as not to disturb the sediment. Decant through a cotton filter, taking care not to pour the sediment on the cotton until the bulk of the liquid has passed through.

This simple procedure with certain brands of peptone and grades of agar gives excellent results.

Procedure No. 2. Where large quantities of agar are to be prepared the following procedure has been found useful. Prepare two separate solutions:

78. Muer and Harris. 1920. Amer. J. Pub. Health 10, 874-875.

79. Kline. 1935. Idem 25, 314-318.

80. Stark and Curtis. 1936. J. Bact 32, 375.

MIXTURE A.

Beef extract, .3 per cent of total quantity of medium to be made.

Peptone, .5 per cent of total quantity of medium to be made.

Distilled water, 40 per cent of total quantity of medium to be made.

Place in a kettle. Weigh kettle with contents. Heat on stove to boiling, and boil five minutes. If absolutely necessary to adjust reaction (see Reaction), do so at this point and boil again. Make up with hot distilled water that lost by evaporation. Do this by weight. Filter through paper or paper pulp in a Buchner funnel. (See below.)

MIXTURE B.

Agar, oven dried, 1.2 per cent (market 1.5 per cent) of total quantity of medium to be made. Soak and wash under tap in sieve. Weigh before and after soaking to determine quantity of water absorbed. Add distilled water, 60 per cent of total quantity of medium to be made, minus that absorbed by the agar during the washing.

Mix A and B (agar not yet melted). Heat mixture over stove, stirring at frequent intervals until agar is entirely melted. Then boil and stir constantly for 20 minutes. Make up weight lost by evaporation, by adding hot distilled water. Keep kettle of agar in chamber of flowing steam while preparing funnel for filtering.

Filter through cotton until clear. For 10-liter amounts it is suggested that either a Sharpless or a nine-inch Buchner funnel with a suction pump be used. The ordinary filtration pump attached to a water faucet producing about 11 inches of vacuum gives good results.

Prepare paper pulp by soaking scraps of ordinary filter paper for 36 to 48 hours in a large wide-mouthed bottle. The paper and water should be in the ratio of six sheets of soft absorbent filter paper (20 by 20 inches) to two and one-half liters of hot water. Moisten the paper and tear it into fragments about one-quarter to one-half inch square. Shake vigorously at intervals to make the suspension fine and uniform. When ready to prepare the nine-inch funnel, take 400 to 500 ml. of the paper pulp and dilute it with about three liters of very hot water. Cut a piece of surgeon's lint (or cotton flannel) to fit the bottom of the funnel exactly. Rinse the funnel with hot water. Place in it the lint with the fleecy side uppermost. Pour in the hot paper pulp suspension carefully so as to cover the lint with an even layer about one-eighth to one-quarter inch thick. Over this lay a disk of filter paper. Place a four-liter suction flask under the funnel and apply the suction to draw the water into the filtration flask until the pulp is firm, yet somewhat moist. The agar will not go through too dry a filter.

The funnel and the paper pulp must be hot when the agar is poured in, carefully and slowly, striking the disk of filter paper which prevents the breaking of the surface of the paper pulp. Discard the first 100 ml. of agar which come through as they contain some of the water from the pulp.

Even in the first filtration the agar should come through very clear. Keep the remainder of the unfiltered agar hot in flowing steam while the first part is running through the filter.

Ordinarily the temperature of the agar in the funnel is 80°C.(176°F.) to 85°C.(185°F.), but the last portions will come through well as low as 50°C.(122°F.) to 55°C.(131°F.).

Keep the filtered agar hot in flowing steam, while preparing a second funnel in the same way as the first. Then filter as before.

Preparation of Nutrient Agar (Standard Methods of Water Analysis). This is the official medium adopted by the American Public Health Association.

Add three grams of beef extract, five grams of peptone, and 15 grams of agar (undried market product as stored in the ordinary laboratory cupboard) to 1,000 ml. of distilled water. Boil until all the agar is dissolved. Cool to 45°C.(113°F.) in a cold water bath, then warm to 65°C.(149°F.) in the same bath, without stirring.

Make up the lost weight with hot distilled water and adjust reaction so that the pH value, after the final sterilization, will be between 6.2 and 7.0.

Bring to a boiling temperature, stirring frequently; restore the lost weight with hot distilled water and clarify. Distribute in the desired containers.

Tryptone-Glucose Extract-Milk Agar (Standard Nutrient Agar) of Standard Methods for Examination of Dairy Products, Eighth Edition. This medium has been adopted as the standard nutrient agar for counting bacteria in milk by the American Public Health Association. It is compounded as follows:

Agar.....	15 gm.
Beef extract.....	0.3 per cent; 3 gm.
Tryptone.....	0.5 per cent; 3 gm.
Glucose.....	0.1 per cent; 1 gm.
Distilled water.....	1,000 ml.

One per cent of skim milk is to be added just before final sterilization in all cases where dilutions greater than one to 10 are made. This medium was proposed by Bowers and Hucker⁸¹ because it permitted higher counts and larger colonies. It has been generally accepted by bacteriologists.

American Association Medical Milk Commissions, Inc.,⁸² Agar Medium. The medium required for determining the bacterial count of certified milk is composed as follows: agar, 1.5 per cent; beef extract, .3 per cent; peptone, one per cent; sodium chloride, .5 per cent; dextrose, .1 per cent; all in distilled water. The final reaction after sterilization shall be pH 6.8 to 7.2. The beef extract and the peptone used shall be such as to give the highest count and the largest colonies. Wilson Nutri-Peptone or a mixture of equal parts of Difco Proteose Peptone and Tryptone were found to be satisfactory. The colonies shall be counted after 48 hours' incubation at 37°C.(98.6°F.). This medium gives considerably higher counts than ordinary agar.

Simmons'⁸³ Citrate Agar Medium. This medium was prepared by adding agar to Koser's citrate medium as follows:

Agar.....	20.0 gm.
Sodium chloride.....	5.0 gm.
Magnesium sulfate.....	0.2 gm.
Ammonium hydrogen phosphate (NH ₄)H ₂ PO ₄	1.0 gm.
Potassium hydrogen phosphate K ₂ HPO ₄	1.0 gm.
Sodium citrate, 2.77 gm. sodium citrate, 5½ H ₂ O.....	2.0 ml.
Distilled water.....	1,000.0 ml.
Brom-thymol blue (1.5 per cent alcoholic).....	10.0 ml.

After dissolving the various salts in sterile distilled water, add 20 grams of clean, washed agar and sterilize the mixture at 15 pounds for 15 minutes in an autoclave. After adjusting the reaction to pH 6.8, add the indicator.

Veal Infusion Agar.⁸⁴ This medium has many uses in practical bacteriology. The formula given here is used as the base for blood agar for detecting presence of streptococci and staphylococci in frozen-egg products. For preparation of blood agar .6 ml. of blood is added per 10 ml. of base medium.

Mix 500 grams of ground lean veal and 1,000 ml. of water. Infuse overnight in refrigerator and strain through cheesecloth without pressure. Make up to original volume with water and skim off any fat. Steam in Arnold 30 minutes and filter through paper. Add peptone (Difco), one per cent or 10 gm.; NaCl, .5 per cent or five gm.; and agar, 1.5 per cent or 15 gm.

Steam in Arnold to dissolve ingredients. Adjust reaction to pH 7.6 and steam in Arnold 15 minutes. Filter through Büchner funnel with paper pulp mat, by aid of

suction. Use egg albumen for clarification when necessary. Add fresh white of one egg previously beaten with 50 ml. of the medium or its equivalent in desiccated egg white (1.5 gm.) to each liter of the medium before adjustment of reaction and after cooling to 50°C.(122°F.). Shake thoroughly to insure solution of egg white. Allow to stand 20 minutes. Heat in Arnold for 15 minutes to coagulate egg white. Shake vigorously and reheat. Filter. Adjust reaction to pH 7.6. Steam in Arnold 15 minutes. Filter. Distribute 10-ml. quantities into test tubes or 80-ml. quantities into bottles. Sterilize at 15 lb. pressure (121°C.) for 20 minutes. Final pH is 7.4. For hemolytic tests, cool melted agar to 40°C.(104°F.) and add six per cent of defibrinated horse, sheep, or rabbit blood prior to pouring plates (.6 ml. of blood per 10 ml. of media).

Pork Extract-Agar Culture Medium.⁸⁵ This was developed in the laboratory of the National Canners Association for making anaerobic spore counts of putrefactive anaerobic bacteria and *Clostridium botulinum*.

Fresh pork shoulder or loin is trimmed of fat and ground; this is then mixed with water, one pound of pork to a liter of water, and boiled for one hour. Sodium hydroxide is used to adjust the reaction to about pH 7.4. When the pork extract is cool, place in a refrigerator so that the fat may be readily removed by hand. After this make up the extract to one liter and add the following ingredients to one liter of extract:

Difco peptone.....	5.0 gm.
Difco tryptone.....	1.5 gm.
Dextrose.....	1.0 gm.
Potassium hydrogen phosphate (K ₂ HPO ₄).....	1.5 gm.
Agar.....	15.0 gm.

Dissolve the ingredients and adjust the reaction to pH 7.4. Place the culture medium in several flasks and sterilize. After sterilization place the medium at 55°C.(131°F.) in a tilted position for several hours, or overnight, during which time a sediment forms in the bottom of the flask. The clear medium may then be decanted from the sediment and tubed and sterilized at 15 pounds pressure for 30 minutes.

Carbohydrate Agar Media. These media are usually made by adding one per cent of the carbohydrate to the agar. As shown by the work of Mudge,³⁶ Hasseltine,³⁵ McAlpine,³⁸ and others, the carbohydrates should probably be sterilized separately. Kleinberger⁸⁶ stated that in making agar shake cultures for determining sugar fermentation, the tubes must be shaken vigorously to distribute bubbles of oxygen, as an abundant supply is very essential except for anaerobes. The time of beginning gas formation and the amount of gas produced depend partly on the number of bacteria in the inoculum, which is opposite for the findings in liquid media. Fermentation activity can be brought to a maximum by passages through the appropriate carbohydrate medium. Bouillon for the preparation of the agar must be made sugar-free by fermentation with *Escherichia coli*. Most carbohydrates should be sterilized separately in 25-per cent solutions and added to the agar just prior to use. The hydrogen-ion concentration which is optimum for a given species must be used and is very important.

Levine⁸⁷ and Burling and Levine⁸⁸ have stated that .5 per cent lactose broth should be used in the presumptive test for coli bacteria in water analysis. With the higher carbohydrate content of the broth, the limiting hydrogen-ion concentration is reached more quickly.

Litmus Lactose Agar (Bendick⁸⁹). Bendick has devised the following for litmus agar:

Agar.....	15 gm.	Lactose.....	1,000 ml.
Beef extract.....	5 gm.	Calcium carbonate	20 gm.
Salt.....	10 gm.	Litmus.....	4 gm.
Peptone.....	10 gm.	Distilled water.....	100 gm.

The agar, beef extract, salt, and peptone are dissolved in 1,000 ml. of water. This is cleared with egg and filtered. No adjusting of the reactions is necessary. This is put into flasks (250 ml. in a 44 ml. flask). One gram of CaCO_3 is added and the whole sterilized. Finally to each flask are added 25 ml. of Kahlbaum's aqueous litmus and five grams of lactose. Tube by pouring direct to the tubes from the flasks and keeping the contents well mixed.

Litmus Lactose Agar. Meyer⁹⁰ has shown that a litmus lactose agar prepared from three per cent agar gives plates which are free from many of the objections incident to plates made from a lesser per cent of agar. The results obtained were approximately equivalent to Endo's medium agar.

Herring Agar. To 500 ml. of the standard herring extract, which is described in another place, were added 500 ml. or 1,000 ml. of sea water, peptone at the rate of one per cent, and agar at the rate of 1.2 per cent. This mixture after heating was prepared for use in the usual manner.

Harde and Hauser's⁹¹ Fish Media. Two media were prepared from flesh of the whiting.

First Medium. The flesh of the whiting is cut into one-milliliter pieces; one such piece is placed in each culture tube and eight ml. of distilled water are added and the medium sterilized at 120°C.(248°F.) for 20 minutes.

Second Medium. Five hundred grams of flesh of the whiting are boiled in 1,000 ml. of water for 30 minutes. This is then filtered through paper and sterilized for 20 minutes at 120°C.(248°F.). This base, after the reaction has been adjusted, may be used for the preparation of agar or gelatin without the addition of other ingredients.

Kulp's⁹² Agar Medium for *Lactobacillus acidophilus*. When studying the effect of tomato juice on the growth of various bacteria, Kulp found that much larger colonies were secured when it was added to a medium having the following composition:

Agar.....	10 gm.
Difco peptone.....	10 gm.
Tomato juice.....	300 ml.
Water.....	700 ml.
Reaction.....	pH 7

The tomato juice is secured by filtering the liquid portion of canned tomatoes through filter paper. The above mixture should be autoclaved to dissolve the agar and finally sterilized at 15 pounds for 15 minutes. Kulp stated that this medium would have a final reaction of about pH 6.5.

Kulp and White's⁹³ Tomato Juice Agar. This medium has been used for examination of acid foods for aciduric spoilage bacteria.

Tomato juice (400 ml.).....	20 gm.
Bacto peptone.....	10 gm.
Bacto peptonized milk.....	10 gm.
Bacto agar.....	12-15 gm.
Distilled water to make 1,000 ml.	

Pour plates fairly thick to provide for subsurface growth.

Milk Powder Agar (Ayers and Mudge⁹³). These investigators have proposed three media prepared from milk powder which they claim have advantages over the ordinary standard agar.

Medium A. Ingredients for one liter.

(a)

- 5 grams of skimmed milk powder
- 250 ml. distilled water
- 1 gram sodium dibasic phosphate (Sorensen's phosphate⁹⁴)
($\text{Na}_2\text{HPO}_4 + \text{H}_2\text{O}$)

(b)

- 5 grams of peptone
- 250 ml. distilled water
- 3 grams meat extract

To make the milk powder solution "a" a good grade of skimmed milk powder should be used. The ingredients of this part of the medium are prepared by placing the five grams of milk powder into 20 ml. of cold distilled water and stirring until dispersed. The phosphate should be dissolved in distilled water and added to the milk powder solution after which the mixture should be heated on a steam bath for about 10 minutes until a grayish precipitate appears. More distilled water should be added and the heating continued; too long heating must be avoided since it will cause a darkening of the medium. Filter and make up to 250 ml. with distilled water.

The extract solution "b" should be prepared and filtered, after which it should be made up to 250 ml. with distilled water. This will give a total volume of 500 ml. to which three per cent of washed agar should be added. No adjustment of the reaction is necessary.

Medium B. The authors have proposed this medium since *Medium A* is slightly cloudy: To make this medium simply substitute in the formula for *Medium A* the following: two grams of peptone and one gram of meat extract instead of five grams of peptone and three grams of meat extract. The medium in other respects is made exactly the same. No adjustment of the reaction is necessary as it will be about pH 7.0 to pH 7.1, brown or slightly brown-red with phenol red.

Medium C. This medium is prepared from washed agar, skimmed milk powder, and yeast extract, as follows:

Ingredients for One Liter of Medium

(a)

- 5 grams of skimmed milk powder
- 1 gram of sodium dibasic phosphate
- 250 ml. distilled water

(b)

- 10 grams of pure dry yeast
- 250 ml. distilled water

Mix "a" and "b" and add 500 ml. of double strength (three per cent) washed agar solution.

The yeast extract should be made from fresh dry yeast which contains no added fillers. To facilitate filtering the yeast should be heated at a temperature of 105°C. (221°F.) to 110°C. (230°F.) for five hours. The extract is made by steaming 10 grams of yeast in 100 ml. distilled water for 45 minutes in an Arnold, then filtering until the filtrate is clear and brilliant. Make up to 250 ml. with distilled water.

The milk powder solution and yeast extract are then mixed and 500 ml. of double strength washed agar (three per cent) are added.

93. Ayers and Mudge. 1920. J. Bact. 5, 565.

94. Sorensen's phosphate is sodium dibasic phosphate with 12 molecules of water of crystallization ($\text{Na}_2\text{HPO}_4 + 12\text{H}_2\text{O}$) which has been air dried so that instead of 12 molecules of water it contains but two molecules.

Milk Powder Agar (Zoller⁹⁵). One hundred and twenty grams of Bacto-Nutrient agar are stirred into four liters of distilled water. Two grams of pure sodium citrate are added and the whole heated in streaming steam for five minutes.

Twenty-five grams of skimmed milk powder are stirred into 100 ml. of distilled water. A thick mixture should be made with the powder and a small amount of water. After all lumps are gone, the remainder of the water may be added.

Stir six grams (1.2 gm. per liter) of disodium phosphate ($\text{Na}_2\text{HPO}_4 + 2 \text{H}_2\text{O}$) into 30 ml. of water and heat to boiling. Add the phosphate solution to the milk powder solution, stir and set in the autoclave and steam for five minutes, while the agar is being melted.

Remove the agar and stir it. Also remove the milk-phosphate solution and add another 50 ml. of distilled water. Replace both the agar and the milk phosphate solution in the autoclave and heat for five minutes at five pounds pressure. Filter the milk phosphate solution through absorbent cotton. Add five grams of lactose to the filtered milk liquid and make up to one liter with distilled water. Mix this milk powder solution with the hot melted agar and place the hot medium in the flasks or bottles destined to receive it. Sterilize at 15 pounds for 15 minutes.

Ayers and Johnson's⁹⁶ Medium for Determination of Coliform Bacilli in Ice Cream. These investigators studied 53 different combinations of ingredients, finally finding that the following was most satisfactory:

Agar.....	1.5 per cent
Asparagine.....	0.3 per cent
Sodium phosphate (dibasic).....	0.1 per cent
Lactose.....	1.0 per cent
Saturated litmus solution.....	2.0 per cent

Muer and Jackson's⁷⁰ Liver Agar:

Beef liver.....	500.0 gm.
Peptone (Witte's).....	10.0 gm.
Dextrose.....	10.0 gm.
Potassium phosphate (K_2HPO_4).....	1.0 gm.
Water.....	1,000.0 gm.

1. Chop 500 gm. of beef liver into small pieces, add 500 ml. of distilled water, and boil slowly for two hours, stirring occasionally.

2. Add five gm. of agar (dried at $105^\circ\text{C}.$ [$221^\circ\text{F}.$] for 30 minutes) to 500 ml. of distilled water and digest for 30 minutes in an autoclave at $120^\circ\text{C}.$ ($248^\circ\text{F}.$) (15 lb.).

3. After making up the loss by evaporation, strain the liver infusion through a wire strainer, add 500 ml. of the filtrate to the agar solution.

4. To the filtrate add 10 gm. of peptone, 10 gm. of dextrose, and one gram of potassium phosphate. Weigh the infusion and container.

5. After warming this mixture in a double boiler and stirring it for a few minutes, to dissolve the ingredients, titrate with N/20 sodium hydrate, using phenolphthalein as an indicator, and neutralize with normal sodium hydrate.

6. Boil vigorously for 30 minutes in a double boiler and five minutes over a free flame with constant stirring to prevent the caramelization of the dextrose.

7. Make up any loss in weight by evaporation, and filter through cotton flannel and filter paper.

8. Tube and sterilize in an autoclave for 15 minutes at $120^\circ\text{C}.$ ($248^\circ\text{F}.$) (15 lb.).

Hasley and Schalter's⁹⁷ Liver Media. One pound of fresh beef liver is ground, and 1,000 ml. of water, 10 gm. of peptone, five gm. of sodium chloride, 25 gm. of agar, and one egg are added; with constant stirring the mixture is heated over a free flame to $70^\circ\text{C}.$ ($158^\circ\text{F}.$); nine ml. of normal sodium chloride solution are added and the container

95. Zoller. 1923. Amer. J. Pub. Health 13, 384.

96. Ayers and Johnson. 1914. Science 39, 802-803.

97. Hasley and Schalter. 1939. J. Lab. and Clin. Med. 24, 523-525.

is placed in an Arnold sterilizer and heated in flowing steam for 60 to 80 minutes; it is then removed, the coagulum loosened from the sides of the container, and allowed to remain at room temperature for five to 10 minutes. If the clot is firm and the liquid is poured slowly, a clear fluid will be obtained without the necessity of filtering, but the authors' routine procedure is to pour the medium through a small amount of glass wool loosely placed in a funnel, to remove the larger particles which may have separated from the coagulum. For liver broth, the ingredients are the same except that no agar is used. Nine ml. of normal sodium hydroxide per liter gives a final pH of 6.6 to 6.8.

Casein Medium (Norris⁹⁸). The use of a dry nutritive powder prepared from caseinogen was proposed. A substrate of 10 per cent caseinogen in an .8-per cent solution washing soda was digested with .5 per cent of pancreatic extract at 37°C.(98.6°F.) for 24 hours. After filtering through muslin, the mixture was concentrated to a thick paste which kept for six months. When it was used in media neither peptone nor meat extract had to be added.

Watson's Sucrose Milk Agar Medium. Watson⁹⁹ used this medium for the study of the intestinal flora. The broth was prepared as follows: Meat extract 1,000 ml., peptone 10 grams, and sodium chloride five grams were mixed and evaporated down to one-fifth of the original bulk and made up to volume with whole milk. Two per cent of sucrose was added after the medium had been neutralized.

Brom-Cresol-Purple Milk of Clark and Lubs.¹⁰⁰ Clark and Lubs proposed substituting brom-cresol-purple for litmus in milk. They found that no change could be observed with litmus which could not be followed equally well with brom-cresol-purple. In some instances, litmus was rendered useless by destruction whereas the brom-cresol-purple continued to function as a good indicator.

The milk was prepared as follows: Add 10 ml. of a .5-per cent solution of brom-cresol-purple to one liter of milk. The concentration of dye should be about .005 per cent. The dye was prepared as follows: .5 gm. was ground to a fine powder and 14 ml. of N/10 NaOH added. Dilute the mixture with 90 ml. of distilled water and then make up to 1,000 ml.

Raw Sugar Cane Juice Agar (Owen¹⁰¹). Fresh raw cane juice should be heated, filtered through cotton, and solidified with two per cent agar.

Raw Sugar Agar (Owen¹⁰¹). This medium was used by Owen in his investigations on the microorganisms in sugar:

Second sugar (80°C.[10%]).....	100 gm.
Tap water.....	1,000 ml.
Agar.....	2 per cent

Raw Sugar Peptone Agar (Owen¹⁰¹):

Second sugar.....	100 gm.
Peptone.....	10 gm.
Agar, two per cent.....	20 gm.
Tap water.....	1,000 ml.

Sucrose Agar of Greig-Smith (Quoted by Owen¹⁰¹). This medium was devised for enumerating the microorganisms in cane sugar products:

Cane sugar.....	10.0 per cent
Potassium chloride.....	0.5 per cent
Sodium phosphate.....	0.2 per cent
Peptone.....	0.1 per cent
Agar.....	2.0 per cent
Reaction + 0.5 Fuller's Scale.

100. Clark and Lubs. 1917. J. Agr. Res. 10, 105-111.
101. Owen. 1914. Louisiana Agr. Expt. Sta. Bull. 146 (Baton Rouge).

Haberman's¹⁰² Molasses Agar Medium for Isolation of Yeasts. The medium consisted of meat extract agar containing eight per cent of sorghum molasses for isolation and two per cent for cultivation and adjusted to pH 5.5 with HCl. *Monilia*, *Trichophyton*, or *Epidermophyton* was recovered from eight of 14 cases of suspected dermatomycosis. Soil cultures gave a greater number and variety of fungi than those on malt agar or Wassman's agar. Pure cultures of *Rhizopus*, *Absidia*, *Penicillium*, *Aspergillus*, *Mucor*, *Alternaria*, and *Cunninghamella* and *Saccharomyces cerevisiae* grew more rapidly, and reproductive structures in most cases appeared earlier than on other media.

Raw Juice Peptone Agar (Owen¹⁰¹):

Fresh filtered raw cane juice.....	1,000 ml.
Peptone, 1 per cent.....	10 gm.
Agar.....	20 gm.

Molasses Peptone Agar (Owen¹⁰¹):

Final molasses.....	160 gm.
Peptone.....	10 gm.
Agar.....	20 gm.
Tap water.....	1,000 ml.

Cameron, Williams, and Thompson's⁷¹ Sulfite Agar Medium for Detecting Presence of Sulfide Spoilage Bacteria. Its preparation was described as follows:

Sulfite agar is prepared by adding .1 per cent sodium sulfite and three per cent sucrose to plain yeast water agar. At the time of tubing, a clean iron strip or nail is placed in the tube. The medium should be used within a week after preparation. Yeast water is prepared by autoclaving at 15 pounds pressure for five hours a 10-per cent suspension of starch-free yeast. This is allowed to settle for several days. When clear, the supernatant liquid is decanted and made into a medium containing 1.5 per cent agar.

A modified sulfite agar medium, developed later,⁸⁴ is prepared as follows: Tryptone 10 gm., sodium sulfite (Na_2SO_3) one gm., agar 20 gm., and water 1,000 ml. At time of tubing, place a clean iron strip or nail in the tube. No adjustment in reaction is necessary. The medium should be fresh as should the sodium sulfite solution also. Sulfide spoilage bacteria form characteristic blackened spherical areas. Owing to solubility of hydrogen sulfide and its fixation by the iron, gas is not noted.

A new medium has been developed in the laboratories of the National Canners Association. In place of the iron strip or nail 10 ml. of a five per cent solution of iron citrate is substituted in the regular sulfite medium formula. It is necessary to heat the citrate solution in order to completely dissolve the citrate. The formula is as follows:

Tryptone.....	10 gm.
Agar.....	20 gm.
Sodium sulfite.....	1 gm.
Water.....	1,000 ml.
Iron citrate*—10 ml. of a five per cent solution.	

* Iron Citrate Merck (Ferric Citrate) U. S. P. III. Pearls.

Dextrose Tryptone Agar for Detecting Presence of Flat-Sour Spoilage Bacteria. This medium resulted from several years' study for a medium which was easily prepared.¹⁰³ Its greatest use has been in examination of canned foods, sugar, and starch for thermophilic bacteria of the *Bacillus stearothermophilus* type. When used for this purpose it must be incubated at 55°C. (131°F.). It has the following composition:

Tryptone.....	10 gm.
Agar.....	15 gm.
Dextrose.....	5 gm.
Water.....	1,000 ml.

102. Haberman. 1938. Amer. J. Clin. Path., Tech. Suppl. 2, 20-22.

103. Williams. 1936. Food Research 1, 217-221.

The reaction should be adjusted to pH 7. It may be bottled in 100-ml. quantities and sterilized at 121°C. (15 lb.) for 30 minutes. Brom-cresol-purple (.004 per cent) should be added before plates are poured. This will give a medium with a purple background in which flat sour-producing bacteria will appear as yellow colonies.

Tryptone-Glucose-Yeast Extract-Agar Medium.¹⁰⁴ This medium has been used for examining fermented foods. Its preparation is as follows:

Agar.....	1.5 per cent
Yeast extract.....	0.3 per cent
Tryptone.....	0.5 per cent
Glucose.....	0.1 per cent
Water, distilled	

The reaction should be adjusted to pH 6.6 to 7.0. The medium is sterilized in the usual manner and distributed into tubes or flasks.

Corn Agar (After Barlow¹⁰⁵**).** This medium was used by Barlow in his pioneer work on flat sour corn caused by thermophilic bacteria.

Corn.....	1,000 gm.
Sucrose.....	80 gm.
Agar.....	60 gm.
Litmus.....	100 gm.
Water.....	4,000 gm.

Stir the corn into the boiling water, add to other materials, boil five minutes, heat in an autoclave and cool slowly; the heavy matter settles off. The clear supernatant agar may be drawn off and tubed.

Potato Decoction Agar (Jensen¹⁰⁶**).** Two average-sized potatoes are washed, pared, and sliced thin. To these are added about two times their volume of water. This is then heated for two hours but never allowed to boil. Filter through cotton and then add 30 grams of agar and five grams of glucose. Cook in the autoclave at 17 to 18 pounds pressure. Distribute into culture tubes, plug, and sterilize in the autoclave at 17 to 18 pounds.

Mickle and Breed⁶⁰ made tomato juice agar medium by adding 10 per cent of tomato juice to ordinary nutrient agar.

Potato-Dextrose-Agar Medium. This medium is used for determination of yeasts and molds in dairy products. It is recommended in *Standard Methods for the Examination of Dairy Products*, eighth edition, page 112. It has the following composition:

Agar.....	1.5 per cent
Glucose.....	2.0 per cent
Infusion from 200 gm. potato.....	1,000.0 ml.

The reaction is adjusted to pH 3.5 ± 0.1 at time of pouring.

The potato infusion is prepared by boiling 200 gm. of sliced potato in 1,000 ml. of water for one hour; then strain through double thickness of clean toweling and restore to original volume. Add glucose and agar and dissolve in the autoclave at 115°C. (239°F.), filter, and distribute in flasks.

Tittsler and Sandholzer's¹⁰⁷ **Peptone-Iron-Agar Medium.** This medium was devised for detection of hydrogen-sulfide formation. The usual method of testing for hydrogen sulfide has been by a lead acetate-agar medium, in which a brownish discoloration is produced along the line of growth. Numerous workers have expressed dissatisfaction with this method. Tittsler and Sandholzer recommend its replacement by peptone iron agar (Difco). In this medium the production of hydrogen sulfide gives rise to an intense blackening, which becomes visible more rapidly than the brownish discoloration in lead acetate agar. In an examination of 376 strains of different groups of bacteria,

104. Amer. J. Pub. Health 33 (1943), 727.
105. Barlow. 1912. Univ. of Illinois, Thesis.
106. Jensen. 1912. N. Y. Agr. Expt. Sta. (Cornell Univ.) Bull. 110.
107. Tittsler and Sandholzer. 1937. Amer. J. Pub. Health 27, 1240-1242.

it was found that the two media gave almost identical results, but that the reaction in the iron medium was very much easier to interpret than that in the lead medium. Its formula is as follows:

Proteose peptone (Difco).....	20.0 gm.
K ₂ HPO ₄ (anhydrous).....	1.0 gm.
Bacto agar.....	15.0 gm.
Ferric citrate.....	0.5 gm.
Distilled water.....	1,000.0 ml.

Dissolve by boiling, put up in deep tubes, and sterilize at 15 pounds for 15 minutes. Inoculate in one or two places between the agar and the glass, carrying the wire to the bottom of the tube.

Brom-Cresol-Purple Agar (Torrey's Modification¹⁰⁸). Five hundred grams of chopped beef heart (other meat material may be used) are boiled in one liter of water for 15 minutes over a free flame. It is then strained through canton flannel or cotton as usual. Make up the loss by adding water and then add 10 grams of peptone and 15 grams of flaked agar. Heat in the Arnold steam sterilizer until dissolved. Adjust the reaction to pH 7.4 and place in the Arnold sterilizer for 30 minutes. Readjust the reaction if necessary. Filter through absorbent cotton and add to the filtrate 10 grams of lactose and sufficient saturated alcoholic solution of brom-cresol-purple (generally about .75 ml.) to give the desired depth of color for a poured plate. Put into flasks in 200-ml. amounts (sufficient for six plates) and autoclave at 15 pounds for 10 minutes.

Hitchin's Agar Medium.³³ To sugar-free broth, add .1 per cent of washed or purified agar; fill into ordinary culture tubes and sterilize. Carbohydrates may be added before sterilization or after separate sterilization in order to avoid hydrolysis. Before inoculation the tubes should be heated in a water bath until a control tube containing one ml. of one per cent methylene blue shows considerable reduction. The tubes may then be cooled to 45°C. (112°F.) and held at that temperature until inoculated. For inoculation, the material should be carried to the bottom of the tube. Indicators such as Andrade's or phenol red may be used.

Enslow's¹⁰⁹ Modification of Hitchins' Agar Medium. This medium was developed in order to adapt Hitchins' medium to fermentation studies. It had the following composition:

Tap water.....	1,800 ml.
Witte's peptone.....	10 gm.
Potassium phosphate (K ₂ HPO ₄).....	17 gm.
Agar.....	2 gm.

For rough indication of fermentation, the mere addition to this medium of the fermentable substance and of a suitable indicator suffices, but for accurate determinations a sugar-free base is necessary. The above materials are heated together in the Arnold for 30 minutes, filtered through paper, and diluted with hot distilled water to 2,000 ml. The hydrogen-ion concentration is then determined and adjustment made with sodium hydroxide. The fermentable substances are added in .5-per cent concentrations. The indicator is brom-thymol-blue and the final pH between 7.2 and 7.6. The medium is tubed in 10-ml. amounts and sterilized by the fractional method.

Another application of semisolid agar was mentioned by Falk, Bucca, and Simmons¹¹⁰ for testing biological products for contamination. When such contaminants as diphtheroids, staphylococci, *Pseudomonas pyocyanea*, and hay bacilli were present in bacterial vaccines, antibacterial serums, antitoxic globulins, and the broth control, media containing .06 to 25 per cent agar were the most dependable for detection of bacterial growth. In addition to the usual .03 per cent glucose biologic products broth, media containing .1 per cent agar was chosen for the routine testing of biologic products for sterility. These experiments confirmed and extended the studies of Hitchins (1921)

109. Enslow. 1923. U. S. Pub. Health Rpts. 38, 2129-2132.

110. Falk, Bucca, and Simmons. 1939. J. Bact. 37, 121-131.

and Spray (1936). Applications to other materials and procedures involving bacterial growth are also indicated.

Spray's Semisolid Media for Cultivation of Anaerobic Bacteria. Spray¹¹¹ used semi solid media for cultivating anaerobic bacteria. Such media contained sufficient agar to check convection currents. It was possible to cultivate the anaerobes without a seal or use of an anaerobic container. Under such conditions cultivation of anaerobes was no more difficult than cultivation of aerobes. The following media were used by Spray.

Anaerobic Plating Medium. Make liver infusion; boil 50 gm. of Bacto liver powder in 1,000 ml. of distilled water. Filter through cotton and make up to 1,000 ml. by pouring hot water through the filter. Adjust the reaction to pH 7.3 to 7.4. To prepare 1,000 ml. of agar medium, take 1,000 ml. liver infusion (above), 77 gm. Difco North gelatin agar, 37 gm. Difco Brain-Heart Infusion powder, and two gm. sodium nitrate.

Boil to dissolve and add water to make one liter. Retitrate and adjust to pH 7.3 to 7.4. Autoclave in a flask and cool to solidify and fix precipitates. When solidified, remelt and add water to make one liter. Tube about eight cm. deep, preferably in 200 x 15 mm. tubes. Autoclave 15 to 20 minutes at 15 pounds pressure.

Spray's¹¹¹ Special Media for Anaerobic Bacteria. The following media were developed by Spray for use in identifying anaerobic bacteria as described in his article in 1936.

Iron-Gelatin Medium for Liquefaction Determination. The medium is composed as follows:

Difco Nutrient gelatin.....	128 gm.
Dextrose.....	1 gm.
Distilled water.....	1,000 ml.

Dissolve in a double boiler to avoid scorching. Adjust the reaction to pH 7.3 to 7.4 and add water to make one liter. Tube about eight cm. deep in 200 x 15 mm., or in 200 x 13 mm. tubes. Add to each tube one strip of iron (as in Iron-Milk) and autoclave as usual. All cultures are incubated at 37°C. (98.6°F.) and are tested daily in ice water—if negative for at least 30 days.

Iron-Milk Medium. Spray recognized five different reactions of anaerobes in this milk medium. It was compounded as follows: Mix fresh whole milk well and tube about eight cm. deep in 200 x 15 mm., or in 200 x 13 mm. tubes. Add to each tube one strip of No. 26 gauge black stove-pipe iron, cut about 50 x 7 mm. Autoclave as usual, but reduce the pressure slowly when completed to avoid wetting or blowing of plugs.

Nitrate Semisolid Agar for Nitrate Reduction. The medium is compounded as follows:

Peptone.....	5.0 gm.
Difco neopeptone.....	5.0 gm.
Agar flakes.....	2.5 gm.
Distilled water.....	1,000.0 ml.

Boil to dissolve and add water to make a liter. Adjust the reaction to pH 7.3 or 7.4; then add:

Potassium nitrate.....	1.0 gm.
Glucose.....	0.5 gm.

Dissolve and mix well. Tube about eight cm. deep in 200 x 15 mm. or 13 mm. tubes and autoclave. The test is performed after 72 hours' incubation, using .6 per cent dimethyl-alpha-naphthylamine with sulfanilic acid, both in dilute acetic acid.

Sugar-Free Fermentation Base¹ Medium.

Neopeptone.....	10.0 gm.
Tryptone, Difco.....	10.0 gm.
Agar flakes.....	2.5 gm.
Distilled water.....	1,000.0 ml.

¹¹¹ Spray. 1936. J. Bact. 32, 135-155.

Boil to dissolve and add water to make one liter. Adjust the reaction to pH 7.3 to 7.4. Andrade or other indicators may be added or omitted. They are usually reduced, although many organisms show typical fermentative reactions. Divide into lots, and add one per cent of the desired sugars. Reserve one lot to be tubed without sugar as a control. Tube about eight cm. deep in 200 x 15 mm., or better 200 x 13 tubes, and autoclave.

Semisolid Stock Culture Medium:

Brain-heart infusion powder, Difco.....	37.0 gm.
Tryptone, Bacto.....	10.0 gm.
Sodium chloride.....	5.0 gm.
Agar flakes.....	2.5 gm.
Distilled water.....	1,000.0 gm.

Boil to dissolve and add water to make one liter. Retitrate and adjust to pH 7.3 to 7.4. Filter twice through cotton with slight suction, and tube about six cm. deep, preferably in 150 x 13 mm. tubes. Autoclave as usual.

Lead Acetate Semisolid Agar Medium. To make one liter, take 36 grams Difco Lead Acetate Agar (two per cent agar). Infuse this for 30 minutes, shaking frequently in one liter of warm (37°C.) distilled water to dissolve all ingredients except the agar. Filter through cotton, with slight suction to remove the agar. Make the volume to one liter by pouring warm water through the cotton filter. Add to this 2.5 grams agar flakes, and boil to dissolve the agar. Make the volume to one liter and adjust the reaction to pH 7.3 to 7.4. Tube about eight cm. deep, and autoclave as usual.

NOTE: Prepared by this method the medium displays quantitatively distinct reactions with the various anaerobes. Spray was unable to reproduce these distinctions by other formulas or other modes of preparation (1936).

Agar Gelatin Medium (North¹¹²):

Lean chopped beef or veal.....	500 gm.
Agar.....	10 gm.
Gelatin.....	20 gm.
Peptone.....	20 gm.
Sodium chloride.....	5 gm.
Distilled water.....	1,000 ml.

Adjust neutral to phenolphthalein. North stated that this medium is excellent for streptococci, pneumococci, and diphtheria bacilli because it is soft and moist and can be used at 37°C. (98.6°F.). It is claimed to be of special value in keeping stock cultures.

Russell's Medium.¹¹³ This medium was devised for studying the colon-typhoid group. It is prepared by adding enough five per cent aqueous solution of litmus to plain agar (two or three per cent) to give it a distinct purple-violet color. Next, one per cent of lactose and one-tenth of one per cent of glucose dissolved in a little water are added and the medium tubed for slants.

On this double sugar tube, *Eberthella typhosa* gives, after an incubation period of from eight to 18 hours, an extremely characteristic appearance; the surface growth is filiform and colorless, the upper part of the tube is unchanged in color, but the lower part is a brilliant uniform red. The entire point of the medium rests upon the difference in the changes produced by the growth of *Eberthella typhosa* under aerobic and under the imperfect anaerobic conditions found in the butt of the tube, where the bacillus obtains its oxygen by breaking down the glucose with the liberation of considerable acid; on the surface, however, in the presence of free oxygen, no acid is formed.

Escherichia coli, which is often slow in producing acid on the Endo plate, shows abundant gas and acid formation on this medium. The tube is reddened throughout, both above and below, and since the abundant lactose is attacked equally with the glucose, there is exuberant gas formation.

The *Bacillus fecalis alkaligenes* and other alkali formers leave the medium unchanged or slightly bluer. The staphylococcus reddens the tube above but leaves it blue below;

112. North. 1909. J. Med. Res. 20, 359-363.

113. Russell. 1911. J. Med. Res. 25, 217.

the *streptococcus intestinalis*, when it grows well, gives a beaded growth and reddens the tube slightly throughout. *B. subtilis*, which is commonly found in feces, usually leaves the medium unchanged but may redden it below without producing gas, yet the heavy, rough surface growth suffices for its differentiation. *B. pyocyaneus* gives a greenish-blue surface growth and leaves the color of the medium unchanged. *B. proteus* produces small gas bubbles in the depth and reddens and then decolorizes the butt very early, while the upper part of the tube is unchanged except for the spreading surface growth.

All dysentery bacilli alter the medium in the same manner as typhoid, yet the quantity of acid produced is small and the reddening is usually confined to the line of inoculation. This reaction is so characteristic that this medium is used in isolating dysentery bacilli; in fact, the same media and technic are used for both typhoid and dysentery.

The paratyphoids leave the upper part of the medium unchanged. The surface growth is like typhoid but in the butt of the tube, in addition to the reddening, are found a few small gas bubbles. The only organisms which may simulate the paratyphoids are slow colons, and these must be thrown out by agglutination tests and further observation of the sugar tube.

Kligler¹¹⁴ stated that by adding .5 per cent of basic lead carbonate to Russell's medium, a good differentiation between *Salmonella paratyphi* and *Salmonella schottmülleri* may be secured. Krumwiede and Kohn,¹¹⁵ by adding one per cent of sucrose to Russell's medium, found that a large percentage of "intermediates" giving a typical paratyphoid reaction could be excluded.

Kligler suggested the substitution of mannite for lactose in Russell's medium for the differentiation of the Shiga and Flexner types of *Shigella dysenteriae* (*Bacterium dysenteriae*). The color changes in Russell's medium for several of the members of the colon-typhoid group are given in Chapter 4. The Digestive Ferments Company prepare a dehydrated Russell's medium which is very satisfactory.

Nichols,¹¹⁶ in the course of some work on the nature of changes in the Russell double sugar culture caused by *Eberthella typhosa*, made the observation that this organism formed carbon dioxide in appreciable amounts. Nichols believed that the characteristic color changes in the Russell medium were due not to direct oxygen requirements but to the retention of carbon dioxide in the butt of the tube and its escape from the slant also to alkaline reversion of other acids. Further work reported by Nichols and Wood¹¹⁷ indicated that carbon dioxide was both respiratory as well as fermentative in origin. Phenol red was said to be the best indicator for this medium since it showed both the acid change in the butt and the alkaline change on the slant when *Eberthella typhosa* was being cultured.

Another attempt to explain the color changes on the Russell double sugar tube was made by Wheeler.¹¹⁸ He mentioned the original explanation of Russell, which involved the oxygen supply, and claimed that it was partly correct. He found that *Eberthella typhosa* fermented all of the dextrose in a Russell sugar tube within 21 hours, regardless of the oxygen supply. This was contrary to Russell's conception of the way in which oxygen produced its effect. Volatile acid production had no direct bearing on the appearance of the Russell double sugar tube. Wheeler stated that the characteristic changes were due to the influence of oxygen on alkali production. In the slant, where oxygen is plentiful, sufficient alkali is produced within 18 to 24 hours to neutralize all of the acid formed by the fermentation of .1 per cent of dextrose, and the slant is alkaline. In the butt, where oxygen is scanty, the amount of alkali produced in 24 hours is not sufficient to neutralize all of the acid formed by the fermentation of .1 per cent of dextrose, and the butt is acid. The alkaline reaction seen in the butt after five to eight days, is due to slow, continued alkali production within the butt, not to a diffusion downward of alkaline substances produced in the butt.

114. Kligler. 1917. Amer. J. Pub. Health 7, 1042-1044.

115. Krumwiede and Kohn. 1917. J. Med. Res. 37, 225-227.

116. Nichols. 1921. J. Infect. Dis. 29, 82-85.

117. Nichols and Wood. 1922. J. Infect. Dis. 30, 321-322.

118. Wheeler. 1924. J. Infect. Dis. 34, 13-38.

Cummings¹¹⁹ recommended undecolorized acid fuchsin for use in Russell's triple sugar-agar medium. He believed that it permitted more clear-cut reactions and exerted no inhibitory effect on bacteria.

Kligler's¹²⁰ Iron Agar for Coliform and Typhoid Organisms. This medium combines the principles of the Russell double sugar agar and Kligler's lead acetate agar into one medium. The Bacto dehydrated medium has the following composition:

Bacto-tryptone.....	20 gm.
Bacto-lactose.....	10 gm.
Bacto-dextrose.....	1 gm.
Ferrie ammonium citrate.....	0.5 gm.
Sodium chloride.....	5 gm.
Sodium thiosulfate.....	0.5 gm.
Bacto-phenol red.....	0.025 gm.
Bacto-agar.....	15 gm.

The reactions on this medium are not unlike those on Russell's double sugar agar.

REACTIONS OF VARIOUS MICROORGANISMS IN KLIGLER'S IRON AGAR (After Digestive Ferments Co.)

Organism	Fermentation reaction		Hydrogen sulfide

* *Eberthella typhosa* usually produces a black ring at the base of the slant, but may be extended.

MacConkey's¹²¹ Agar Medium. This medium has been used for many years in Great Britain in sanitary work. The following formula is taken from *The Bacteriological Examination of Water Supplies* of the Ministry of Health of London.

Commercial sodium taurocholate.....	5 gm.
Peptone.....	20 gm.
Sodium chloride.....	5 gm.
Washed shredded agar.....	20 gm.
Distilled water.....	1,000 ml.

Steam until the solids are dissolved. Cool to 50°C.(122°F.) and adjust the reaction at 50°C. to pH 7.6 or 7.8. Add egg white, using the albumen from one egg for every three liters of medium. Autoclave at 10 pounds pressure for 15 minutes and filter hot through Chardin paper. Adjust the reaction of the filtrate at 50°C. to pH 7.3 or at room tem-

120. Kligler. 1918. J. Expt. Med. 28, 319.

121. MacConkey. 1905. J. Hyg. 5, 333.

perature to pH 7.5. Add 10 grams of lactose and about 10 ml. of a one-per cent neutral red solution. Mix thoroughly, distribute into flasks, and sterilize.

Violet Red Bile Agar. This medium was developed by the Digestive Ferments Company for counting coliform bacteria in water, milk, dairy, and food products directly. The Bacto-product has the following composition:

Peptone.....	10 gm.
Lactose.....	10 gm.
Bile salts.....	1 gm.
Yeast extracts.....	5 gm.
Agar.....	15 gm.
Neutral red.....	0.05 gm.
Crystal-violet (DC-1).....	0.004 gm.

This medium has been favorably reported on by several investigators.¹²²

Nichols and Wood's¹¹⁷ Modification of Russell's Double Sugar Medium. Make a three-per cent extract agar; clear; add one per cent of lactose, .1 per cent of glucose, and five per cent of a .2-per cent water solution of phenol red. Correct the reaction to pH 7.2 to 7.4 while the medium is hot. Tube, sterilize, and slant in such a manner that there is a deep butt with a long slant.

Krumwiede and Kohn's¹¹⁵ Modification of Russell's Double Sugar Medium. This modification of the Russell medium consisted in adding one per cent of sucrose. The medium had the following composition:

Peptone.....	10 gm.
Agar.....	15 gm.
Lactose.....	10 gm.
Sucrose.....	10 gm.
Dextrose.....	1 gm.
Sodium chloride.....	5 gm.
Andrade's indicator.....	.025 gm.

Adjust to neutrality.

Kendall and Ryan's¹²³ Double Sugar Agar. A double sugar agar containing sucrose and mannitol for use along with Russell's medium was proposed. It was used in the identification of intestinal bacteria. The medium is prepared as follows: One per cent of sucrose and .1 per cent of mannitol are added to 2.5 per cent of nutrient agar and the reaction adjusted so that Andrade indicator is faintly pink when hot. One per cent of Andrade indicator is added to the medium and the medium sterilized either in the autoclave or Arnold steam sterilizer. The tubes should be slanted, leaving a butt at the point where the slanted surface begins, of about one cm. in depth. This medium will distinguish between the bacteria that act on sucrose and mannitol.

Jordan and Harmon's¹²⁴ Medium for Differentiating Paratyphoid Group. This medium was proposed to obviate some of the disadvantages of Brown, Duncan and Henry's medium. Jordan and Harmon's medium will give a perfectly definite differentiation between *Salmonella aertrycke* and *Salmonella schottmülleri*. Its preparation was described by Jordan and Harmon as follows:

Agar.....	20 gm.
Difco peptone.....	10 gm.
Sodium potassium tartrate (Rochelle salts).....	10 gm.
Sodium chloride.....	5 gm.
Distilled water.....	1,000 ml.
Alcoholic solution of phenol red (0.2%).....	12 ml.

The medium should be adjusted to a pH of 7.6 to 7.8 and is best used in tubes unslanted, a stab inoculation being made. Observations should be made at 24- and

122. Bartram and Black. 1936. Food Research 1, 551; Babel and Parfitt. 1936. J. Dairy Sci. 19, 497; Miller and Prickett. 1938. Idem 21, 559.
123. Kendall and Ryan. 1919. J. Infect. Dis. 24, 400-404.
124. Jordan and Harmon. 1928. J. Infect. Dis. 42, 238-241.

48-hour intervals, although the reaction in tubes is generally stable, for at least seven days. The paratyphoid strains that impart an acid reaction to the medium give a distinct yellow color in the lower portion of the tube, with a surface zone of from four to seven mm. which remains red, while those strains that produce an alkaline reaction give a diffuse homogeneous reddish coloration.

Huntoon's¹²⁵ Hormone Agar. This medium containing chopped beef heart or steak is supposed to contain certain agents which favor the growth of bacteria. They are probably erroneously called "hormones." The method of preparation was described as follows:

Chopped beef heart or steak (must be comparatively fresh)	500 gm.
Water.....	1,000 gm.
Peptone (Bacto peptone).....	10 gm.
Agar (Bacto Agar).....	16 gm.
Salt.....	5 gm.
Whole egg.....	1 gm.

All of the ingredients are placed in an ordinary enamelware vessel, preferably a large coffee pot, and heated over an open flame with constant stirring until the red color of the meat infusion changes to brown, at a temperature of about 68°C.(154.4°F.). Care should be taken not to run the temperature much above this point as the medium then begins to clot, which is undesirable at this time.

The medium is now titrated with normal sodium hydroxide until it is slightly alkaline to litmus paper and then one ml. per liter is added in addition.

The vessel is covered and placed in the Arnold sterilizer or in a water bath at a temperature of 100°C.(212°F.) for one hour, removed, and the firm clot which has formed is separated from the sides with a rod and the vessel returned to the sterilizer or water bath at 100°C.(212°F.) for one and one-half hours.

It is removed and allowed to stand at room temperature for about 10 minutes in a slightly inclined position; during this time the fluid portion separates and may be removed by pipetting or, in case of the coffee pot, by simply pouring it off carefully. If it is poured through a fine wire sieve, many small particles of meat clot may be caught.

The product is allowed to stand in tall cylinders for 15 to 20 minutes, until the fat present has risen to the surface where it can be removed. The medium is tubed and sterilized by the intermittent method. Autoclaving is to be avoided.

If the medium, although usually clear enough for practical purposes, seems too turbid, further clearing may take place by filtration through glass wool, asbestos wool, sedimentation, or centrifugalization.

Huntoon's Semisolid Agar Medium. This medium is prepared like the medium just described with the exception that five grams instead of 16 grams of agar are used. This medium is tubed in 10-ml. amounts and employed for stab inoculations. Huntoon stated that it was especially suited for preservation of stock cultures.

Bailey's⁶⁰ "Hormone" Agar. A medium rich in accessory substances was described as a "hormone" medium. It was prepared as follows:

1. Dissolve in one liter of distilled water 15 gm. of agar shreds which have previously been washed thoroughly in running water and allow to cool between 50°C. (122°F.) and 60°C.(140°F.). This step we believe to be important, because it reduces the amount of heating necessary after the addition of the meat and brings the agar suspension into contact with all of the meat particles before any coagulation has occurred.

2. Add 500 gm. of lean beef or beef heart (chopped to moderate fineness), bring to a boil, and cook slowly for 15 or 20 minufes.

3. Filter through an ordinary round flour sieve (colander type) about 16 mesh to the inch. Allow the agar and meat mixture retained on the sieve to become more or less evenly spread out, so that it acts as a filter, and again pour the filtrate through it. Filtration carried on in this way occurs with sufficient rapidity to allow several filtra-

125. Huntoon. 1918. J. Infect. Dis. 23, 169-172.

tions before cooling, if such are necessary to make the medium entirely clear. Egg need not be used.

4. Add peptone, 10 gm., and sodium chloride, five gm. Boil for about five minutes.

5. Correct to the desired reaction (pH 7.5).

The sodium hydroxide used to correct the reaction is likely to cause a brownish discoloration of the medium if it is added before the meat is removed by filtration. This does not occur when it is added after the meat has been filtered out.

6. Allow to stand in a warm place for a few minutes until the precipitate produced by the hydroxide settles out, and then decant the supernatant fluid.

With this procedure little precipitate is formed and little waste occurs.

7. Tube and sterilize by the fractional method or autoclave for about 20 minutes at five pounds of pressure.

It has been found that the medium is not damaged by autoclaving at low pressure, and a practice may be made of autoclaving tubed medium once and the medium in flasks twice.

Crystal Violet Agar (Salle¹²⁶). Salle proposed this medium for differentiating *Escherichia coli* and *Aerobacter aerogenes*. The results were said to be equivalent to a confirmed and partially confirmed test as provided for in *Standard Methods for the Examination of Water and Sewage*. Salle described its preparation as follows:

Peptone, Difco.....	5.0 gm.
K ₂ HPO ₄	5.0 gm.
KH ₂ PO ₄	1.0 gm.
Agar.....	20.0 gm.
Distilled water.....	1,000.0 ml.

No adjustment of the reaction is required. This is controlled by the buffer substances. The ingredients are mixed and boiled until the agar is dissolved. The loss of water owing to evaporation is restored. The agar is not filtered, but distributed directly into 250 ml. Erlenmeyer flasks, 100 ml. to each flask. When ready to use, .5 gram lactose is added to each flask, and the agar melted in an Arnold sterilizer or in boiling water. After the agar is melted the following dyes are added to the contents of each flask: erythrosin (two per cent aqueous), two ml.; methylene blue (one per cent aqueous), one ml.; and brom-cresol-purple (one per cent aqueous), two ml. The agar is rotated in the flask to obtain a uniform mixture and then poured into sterile petri dishes.

Salle gave instructions for the preparations of the dye solutions. While the composition of different lots and brands may vary, this matters little for methylene blue and brom-cresol-purple. The erythrosin, however, caused considerable trouble. Instructions were given by Salle in his original report for preparing these solutions.

The growth of coliform bacilli on Salle's medium, which contains erythrosin, was found to be very irregular by Liebert and Kaper.¹²⁶ When no growth at all occurred, the medium was observed to be slightly discolored. Investigations showed that this was due to the effect of light. The strongly fluorescent erythrosin apparently converted the shorter light waves (not necessarily ultra-violet) into longer waves with the accompanying production of hydrogen peroxide. Other dyes, such as eosin and fluorescein, had a similar effect. If the medium is exposed to light before inoculation, sufficient hydrogen peroxide may be formed to inhibit growth entirely. Bacilli exposed to light in the presence of these dyes may be killed by the intracellular production of hydrogen peroxide from the dye which the organisms have absorbed.

Salle's phosphate buffered broth, containing one part crystal violet to 700,000 parts water, was tested by Stark and England¹²⁷ on seven laboratory stock strains of the *Escherichia-Aerobacter* group, and on 164 *Escherichia*-type organisms recently isolated from human feces. Forty-three per cent of these fecal cultures gave negative results

126. Liebert and Kaper. 1937. *Antonie van Leeuwenhoek Nederland. Tijdschr. v. Hyg. Microbiol. et Serol.* 4, 164.

127. Stark and England. 1933. *J. Bact.* 25, 439-445.

after 48 hours' incubation at 37°C.; all gave positive results in standard lactose broth. Cultures producing negative results in 48 hours eventually produced gas, some requiring as long as five days for 10-per cent gas to be produced; the organisms were not killed, but growth was delayed. Results tend definitely toward the conclusion that Salle's crystal-violet broth should not be adopted as a standard test medium in water analysis. To maintain the proper margin of safety, no medium should be used, which sometimes gives negative results in presence of fecal pollution.

Chapman and Berens¹²⁸ observed that staphylococcus strains plated on proteose-lactose agar containing a final concentration of 1-300,000 crystal violet (National Aniline and Chemical Company) gave rise to white colonies, violet colonies, or orange colonies having usually a violet fringe. As a rule the strains giving rise to either of the latter two types of colony were hemolytic, produced coagulase, and were toxic to rabbits on intravenous inoculation; while strains giving rise to white colonies were negative in all these respects. The agreement was not perfect, but was sufficiently good to justify the authors in their conclusion that the colonial appearance on crystal violet agar should be of considerable help in differentiating pathogenic from non-pathogenic strains of staphylococci.

Tonney and Noble's¹²⁹ Improved Ferrocyanide-Citrate Agar for Direct Enumeration of Colon-Aerogenes Organisms. This medium was first proposed in 1928. The modified medium was reported in 1931 as follows:

I. PREPARATION OF STOCK MEDIUM AND "COVER" AGAR.

Many laboratories will find it more convenient and economical to prepare the stock medium in 10-liter, or larger, quantities. On this basis, the following formula, one and one-half times the required strength, is given:

Distilled water.....	20 liters
Agar, shredded.....	300 gm.
Sodium ammonium phosphate, C. P.....	30 gm.
Acid potassium phosphate (KH ₂ PO ₄) C. P.....	15 gm.

Procedure

1. Three hundred grams of shredded agar are placed in a cheesecloth bag of four thicknesses.

2. The bag of agar is then placed in a container of approximately six gallons capacity and 20 liters of distilled water added. After 24 hours, discard the free water and press the water from the agar by twisting and squeezing it. Replace bag in container and add 20 liters more of distilled water. This process is repeated until the end of the fourth 24-hour period. After the batch has been drained as usual, rinse the container and empty the agar from the bag into the container. Then add more distilled water to make a three-per cent agar for stock or the two-per cent agar and water "cover" as needed.

3. If the autoclave is not large enough to receive the large container, transfer the batch to two smaller containers with covers and mark the water level for the purpose of replacing loss by evaporation. Melt the agar in the autoclave.

4. Replace loss by evaporation. Add 30 grams of sodium ammonium phosphate, C. P. and 15 grams of acid potassium phosphate, C. P. to the batch and mix thoroughly. The salts readily dissolve. If two containers are used, add salts as above and pour the contents of containers back and forth to assure the same concentration throughout.

5. Adjust the reaction to pH 7 with brom thymol blue.

6. Filter the agar through a sterile filter and deliver measured quantities by sterile graduate into presterilized plugged bottles. Any convenient quantity may be measured. We have found it convenient to put 140 ml. in a bottle. This quantity fits in well with convenient amounts of solutions A and B. Bottles are then paper capped for protection and steamed in the Arnold for 15 minutes only.

128. Chapman and Berens. 1935. Jour. Bact. 29, 437-448.

129. Tonney and Noble. 1928. Amer. Water Wks. Assoc. J. 23, 1202-1208.

7. The two-per cent agar in distilled water is merely melted, filtered, distributed into presterilized plugged containers, and autoclaved.

II. PREPARATION OF STOCK SOLUTIONS A AND B.

*Solution A. (One liter.)**

Anhydrous sodium sulfite. Na_2SO_3 C. P.....	3.8 gm.
Acid potassium phosphate. KH_2PO_4 C. P.....	7.5 gm.
Sodium ammonium phosphate. $\text{NaNH}_4\text{HPO}_4 \cdot 4\text{H}_2\text{O}$ C. P.....	45.4 gm.
Distilled water, sterile.....	817.0 ml.
20% lactose, sterile.....	140.0 ml.
4% alcohol (95%) basic fuchsin.....	18.0 ml.
9% potassium ferrocyanide. $\text{K}_4\text{Fe}(\text{CN})_6 \cdot 3\text{H}_2\text{O}$ C. P.	
steamed in streaming steam 15 minutes.....	25.0 ml.

Procedure

1. Add 4.6 grams of anhydrous sodium sulfite, C. P. to a two-liter flask.
2. Add 167 ml. of sterile distilled water and bring to a boil avoiding unnecessary loss of moisture by evaporation. (Boiling also may be accomplished in smaller containers of glass, porcelain, or granite ware and then transferred to the stock flask.)
3. Cool and add 421 ml. of sterile 20-per cent lactose solution, C. P. If the latter has been stored at low temperature, it will assist in cooling the heated sulfite solution.
4. Add 8.8 ml. of a saturated alcoholic (95%) solution of basic fuchsin.
5. Add 401 ml. of sterile 20 per cent potassium ferrocyanide solution C. P.

Stock solution B consists of 2.5 per cent ferric citrate; 400 ml. will be required for use in conjunction with one liter of solution A.

The concentration of ingredients in Solutions A and B is one and one-half times the required strength for use in planting 10 ml. portions of an equal ratio with three per cent stock agar, resulting, of course, in two per cent agar having ingredients of single strength.

III. ADDITION OF SOLUTIONS A AND B TO STOCK AGAR AND POURING OF PLANTED PLATES.

1. On the basis of using 20 ml. of stock medium and 10 ml. of "cover" agar per plate, determine the number of bottles of medium and cover needed and melt in the Arnold or in a container of water over a free flame.

2. Set up and label the necessary number of petri plates. To those plates which are to receive one ml. or less of inoculant, add 10 ml. of sterile distilled water.

3. To each bottle of melted stock agar add (a) 12.5 ml. of Solution A and agitate thoroughly; (b) five ml. of Solution B and agitate thoroughly. Hold the bottles of cyanide citrate medium in a container of water or water bath between 47 and 60°C. (116.6 and 140°F.). Keep the "cover" agar warm enough to pour when ready.

4. Plant the plates. This is done while the medium is cooling down or being held at a given temperature.

5. With the cyanide citrate agar at low enough temperature to be harmless to the organisms and high enough to avoid too rapid solidification while mixing with the cool or cold inoculant (probably 46 to 47°C. will be about right), add 20 ml. water to the plate and mix thoroughly. This is easily accomplished by slightly lifting one side of the cover.

6. When plates have hardened, add 10 ml. of "cover" agar. This may be pipetted or poured, provided fair judgment of amount is used. A little more or less is of little consequence, except that when too thin some colonies may come through and spread, thus hiding a deeper one which may thus be lost in the count. When the "cover" has hardened, invert the plates in a 37°C. incubator for 42 to 48 hours.

* This formula from a private communication. November, 1931.

7. Count the plates by means of a standard hand lens and counting frame having a white background affording transmitted light by illumination from the sides.

According to Tonney and Noble¹³⁰ some of the practical advantages of the direct plating method in cyanide-citrate agar are as follows: It has greater simplicity than fermentation methods (consists only of planting the plates and counting them after incubation); it yields results in a shorter time (completed observations in 42 to 48 hours, presumptive indications in 36 hours); it gives separate *Escherichia coli* and *Aerobacter aerogenes* counts and their numerical relation to each other, as well as the total count; it gives a more accurate index than is obtainable by use of liquid media. Direct counts are not obscured by overgrowths and are not interfered with by other common lactose-fermenting organisms, such as *Clostridium welchii* or *Bacillus aerosporus*. The "pour plate" process is an excellent method of isolating pure cultures of *Escherichia coli* and *Aerobacter aerogenes*. Deep colonies fished from a poured plate are apt to yield pure strains.

Sodium Desoxycholate Agar Medium. The American Association of Medical Milk Commissions⁸² recommends preparation of this medium as follows:

Distilled water.....	1,000 ml.
Peptone.....	10 gm.

Boil for a short time and filter through paper. Neutralize if necessary. Add the following:

Agar (granular, U. S. P.).....	17 gm.
Sodium hydroxide (N/1).....	2 ml.

Heat in the Arnold steamer or the autoclave until the agar is dissolved. If the autoclave is used, restore the volume of the medium with distilled water. Add the following substances in the order given:

Sodium desoxycholate.....	1 gm.
Sodium chloride.....	5 gm.
Dipotassium phosphate.....	2 gm.
Lactose.....	10 gm.
Ferric ammonium citrate, ferric sodium citrate, or ferric potassium citrate.....	2 gm.

Adjust the reaction to pH 7.5 and add

Neutral red (certified; 1% aqueous sol.).....	3.3 gm.
---	---------

Tube and sterilize for 15 minutes in the Arnold steamer, longer if distributed in flasks. Autoclaving is not necessary because Gram-positive sporeforming bacteria do not grow in the medium. The medium should be heated as little as possible and only sufficiently to kill vegetative cells. Store in the dark because neutral red is decolorized by light. The following peptones have been found satisfactory: Proteose (Difco), Wilson, Nutri, Fairchild, Witte, and Armour; the following were less satisfactory, Bacto (Difco), Neo (Difco).

American Association of Medical Milk Commissions,⁸² Blood Agar Medium. The blood agar medium shall be prepared as follows:

Finely ground lean pork, veal, or beef.....	500 gm.
Distilled water.....	1,000 ml.
Peptone.....	10 gm.
Sodium chloride.....	5 gm.
Granulated agar, U. S. P.....	15 gm.

Mix the meat with the water, infuse for one hour, and then boil for five minutes. Strain through wire or cotton gauze and filter through paper. Restore the volume to 1,000 ml. Add the peptone and the salt. Adjust reaction to pH 7.8. Boil for 15 to 20

82. Methods and Standards for Production of Certified Milk, Amer. Assoc. Med. Milk Comm. 1939, p. 18; see also Leifson. 1935. J. Path. and Bact. 40, 581.

*Growth and Appearance of the Colonies of Various Types of Bacteria on Desoxycholate and Desoxycholate-Citrate Agars*¹³¹

Bacteria	Desoxycholate agar	Desoxycholate-citrate agar
Coli	Large colonies with even red color	Considerably inhibited. Colonies like those on desoxycholate agar
Aerobacter	Large mucoid colonies having pink centers and colorless peripheries	Considerably inhibited. Colonies like those on desoxycholate agar
Proteus	Large, non-spreading, smooth colonies, with touch of brown in center	Many strains inhibited. Colonies develop brown centers
Alkaligenes	Large, smooth, colorless colonies	Usually no growth
Pyocyaneus	Large olive-colored colonies with raised centers and diffuse edges	Large, olive-colored, slightly granular, opaque colonies
Typhoid	Large colorless colonies (where isolated) with raised center and irregular thin edges	Fairly large, translucent, bluish-looking colonies, with slightly granular structure
Paratyphoid "A"	Large, smooth, colorless colonies	Large translucent colonies, somewhat more smooth and more regular edges than typhoid
Salmonella in general	Large colorless colonies, usually with touch of brown in center	Large, colorless, opaque colonies, usually with touch of brown in center
Dysentery—Flexner	Large, smooth, white and opaque colonies with smooth, even edges	Large, colorless, milky opaque, smooth colonies with even edges
Dysentery—Sonne	Same as Flexner type	No growth (?)
Dysentery—Shiga	Same as Flexner type but smaller	No growth (?)
Gram-positive bacteria	No growth	No growth

minutes. Filter through paper and restore volume or weight. Add the agar and heat to boiling with constant stirring. Add five ml. of N/1 NaOH. Autoclave for 15 minutes. Restore the weight with boiling water and stir well. Place a sterile lid over the vessel and allow the medium to sediment at room temperature overnight. Next morning spoon off the clear agar from the surface or remove the solidified agar from the vessel and cut off and discard the sediment. Melt, distribute into tubes or flasks, and sterilize in the autoclave. The final reaction should be pH 7.2 to 7.6. (It is recommended that several liters of agar be prepared at one time.)

Hall and Lothrop's¹³² **Honey Agar.** Aggregates of flocculated materials, normal to honey agar, were eliminated by preheating honey with a suspension of colloidal clay—bentonite. The nutritive values of honey agars made from clarified honey of three floral types (tupelo, fruit bloom, and clover) were compared with those of honey agars made from the same honeys without clarification. Five cultures of sugar-tolerant yeasts were selected for plate and slant studies. The diameters (in mm.) and total numbers of colonies developing on plates poured with clarified *versus* unclarified honey agars were equal, within the limits of accuracy for dilution-plate methods. The amount of yeast growth on honey-agar slants made with clarified honey approximated that on slants made with unclarified honey. Cultural and physiological characteristics of yeast propagated on clarified honey agar remained unaltered.

131. From publication of Baltimore Biological Laboratory.

132. Hall and Lothrop. 1934. J. Bact. 27, 349-355.

Eisenberg's¹³³ Nile Blue Culture Medium for Lipolytic Microorganisms. This medium makes use of Nile blue sulfate as an indicator for detecting changes in neutral fats. Its preparation and use were described as follows:

PREPARATION OF THE MEDIUM

(a) Dissolve 20 gm. agar (Bacto) in 1,000 ml. of beef infusion broth prepared according to the directions of Zinsser and Bayne-Jones (1935). Filter through absorbent cotton and adjust the reaction to pH 7.4. Distribute in 100-ml. amounts in flasks and sterilize in the autoclave at 15 pounds pressure for 20 minutes.

(b) *Dye-Fat Emulsion*: Dissolve four gm. ossein gelatin (200 Bloom, isoelectric point at pH 5.6) in 100 ml. of distilled water at 60°C.(140°F.). Add sufficient N/10 NaOH solution to raise the pH to 7.2. The gelatin solution, while still warm, is shaken vigorously in a large stoppered bottle with 100 ml. of cottonseed oil (U.S.P.) to which has been added .1 gm. Nile blue sulfate (C. I. No. 913, dye content 90 per cent, solubility .15 gm. in 100 ml. water). The mixture is then put through a hand homogenizer until the oil globules are about 10 microns in diameter. This emulsion has a light blue color and after sterilization in the autoclave at 15 pounds pressure for 20 minutes turns deep pink. At room temperature the emulsion solidifies, but by placing it in the incubator at 37°C.(98.6°F.) a day before it is to be used no difficulty in pipetting is experienced.

(c) *Preparation of Plates*: When plates are to be poured 100 ml. of the sterile infusion agar base are liquefied, and while still hot, 10 ml. of the sterile dye-fat emulsion are added aseptically. The whole is well mixed and allowed to cool at 45°C. (113°F.) before being poured into plates. Before inoculation the medium has a rich salmon-pink color.

The medium is equally efficient both with pour and streak plates, the former being desirable for quantitative work. Colonies of organisms which decompose fats appear as light blue colonies surrounded by a narrow zone of decolorized, transparent medium when incubated for three to four days at room temperature. Non-lipolytic colonies appear white or pink.

Starr's¹³⁴ Spirit Blue Agar for Detection of Lipolytic Microorganisms. Starr suggested a sensitive differential medium which is easy to prepare, is not toxic to bacteria, and permits "indisputable detection of fat-splitting microorganisms." The preparation is as follows: Dissolve 30 gm. agar, 10 gm. tryptone, and five gm. yeast extract in approximately 900 ml. distilled water, by autoclaving; to this add 25 ml. of a 20-per cent cottonseed oil emulsion (10 gm. powdered gum arabic ground thoroughly in 100 ml. Wesson oil and 400 ml. warm distilled water) and 50 ml. of .3-per cent freshly filtered alcoholic spirit blue (National Aniline); bring up to 1,000 ml. with distilled water, and autoclave 15 minutes at 15 pounds (121°C.). The medium must be stored in a refrigerator until used. Plates made from it appear pale lavender; lipolysis is indicated by a permanent deep blue beneath and around the colony.

Turner's¹³⁵ Differential Plating Medium for Lipase-Producing Bacteria. This medium causes the lipase-producing colony to show a dark-blue zone about it. It is composed as follows: Sugar-free meat digest fluid, 1,000 ml.; dibasic sodium phosphate, five gm.; agar, 30 gm.; melt clear and adjust to pH 7.6. Autoclave. Add 1.25 gm. of Nile blue sulfate in 100 ml. of 25-per cent ethyl alcohol. Tube in six- to seven-ml. amounts in previously sterilized tubes. Heat in the Arnold sterilizer for 15 minutes. When used the agar is melted and cooled to 45 to 50°C.(113 to 122°F.). A sterile emulsion of fat is added to about 10 per cent volume; .7 ml. for seven-ml. tube. Cream of cottonseed oil made according to the directions of the U. S. Pharmacopeia for codliver oil, except 25 per cent more water is used than prescribed, may be used. The inoculum and emulsion are thoroughly mixed with agar, poured into a Petri dish, and allowed to harden. The plates should be incubated under anaerobic conditions. The typical colony is apparent after 24 hours. Streak plates are not satisfactory.

135. Turner. 1928. Soc. Expt. Biol. and Med. Proc. 25, 318-320.

Jensen and Grettie's ¹³⁶ modification of emulsion medium, which may be incubated either at 20°C.(68°F.) or 37°C.(98.6°F.), was made as follows:

Agar stock

Nutrient agar 100 ml.
 Na_2HPO_4 $\frac{.5 \text{ gm.}}{\text{pH } 7.4}$

Oil emulsion

100 ml. refined coconut oil (or palm oil), two gm. gum tragacanth added to hot distilled water, 200 ml. Shake until the globules are about 10 μ in diameter. Autoclave at 15 pounds for 15 minutes.

Jensen and Grettie then added .75 ml. of the oil emulsion and .75 ml. of .1 per cent Nile blue sulfate aqueous solution to each five and one-half ml. of melted agar. Portions of the well-mixed medium are then cooled to 42°C.(107.6°F.), the inocula in dilutions added, and plates poured in thin layers. The lipase-forming colonies are, at first, deep blue in color.

Reed and Orr's ⁵⁹ Plating Medium for Anaerobes. They added .1 per cent of dextrose and two per cent of agar to the sugar-free broth of Breiner, described above.

A second formula was proposed as follows:

Proteose peptone.....	20.0 gm.
Sodium phosphate.....	2.0 gm.
Dextrose.....	1.0 gm.
Sodium thioglycollate.....	1.0 gm.
Agar.....	20.0 gm.
Water.....	1,000.0 ml.
Adjust to pH 7.6.	

The plates were incubated upright in a Fildes jar.

Greenberg's ¹³⁷ Semisolid Agar Medium for Isolating Anaerobic Bacteria. This medium was proposed as especially useful for this purpose.

Proteose peptone.....	10 gm.
Tryptone.....	10 gm.
Sodium thioglycollate.....	1 gm.
Agar.....	3 gm.
Distilled water.....	1,000 ml.

Adjust the reaction to pH 7.4, dispense in tubes in 10-ml. amounts, and autoclave at 15 pounds for 20 minutes.

Proteose Peptone Acid Medium of Stern, Hegarty, and Williams.¹³⁸ This medium was devised for isolation of *Bacillus thermoacidurans* from canned tomato juice. The following composition proved to be most satisfactory:

Proteose peptone (Difco).....	5 gm.
Yeast extract (Difco).....	5 gm.
Glucose.....	5 gm.
K_2HPO_4	4 gm.
Distilled water.....	500 ml.

The ingredients are dissolved in the water, and the pH adjusted to five with dilute HCl. In a separate flask 20 grams of agar are dissolved in 500 ml. of water, and then both solutions are sterilized for 30 minutes at 15 pounds pressure. When the medium is ready to be used, the melted agar is mixed with the sterilized nutrients at 45 to 55°C. (113 to 131°F.).

ENDO'S MEDIUM

This medium was reported by Endo¹³⁹ as especially suitable for differentiation of *Eberthella typhosa* from *Escherichia coli*. Since the original medium was proposed, there have been many modifications. Young and Marshall¹⁴⁰ have stated that many of them are not as satisfactory as the original formula.

Endo's Medium (after Kendall¹⁴¹):**I. PREPARATION OF AGAR**

- (a) Prepare plain, sugar-free agar, using 15 gm. agar per liter.
- (b) Adjust to a point just alkaline to litmus.
- (c) Place in flasks in 100-ml. quantities and sterilize.

II. PREPARATION OF THE INDICATOR

- (a) Prepare a 10-per cent basic fuchsin solution in 96-per cent alcohol. This solution is fairly stable if kept away from the light.
- (b) Prepare a 10-percent solution of chemically pure anhydrous sodium sulfite. (One gm. in 10 ml. water.) This solution does not keep.
- (c) Add one ml. of II (a) to 10 ml. of II (b) and heat in the Arnold sterilizer for 20 minutes. The color of the solution should be nearly discharged. This solution must be prepared each day. It does not keep.

III. PREPARATION OF MEDIUM

- (a) Add one gm. of lactose to 100 ml. of the agar and place in the autoclave until melted and lactose is dissolved.
- (b) Add enough of II (c) to impart a pink color (about one ml.).
- (c) Pour into sterile Petri dishes and allow to harden. In the above medium Kendall has reduced the agar content to 1.5 per cent. The original formula of Endo called for a three-per cent solution which was supposed to prevent diffusion of the acid.

Endo's Medium (Hygienic Laboratory Method). Hasseltine¹⁴² has described the preparation of this medium as follows: It consists of a three-per cent agar which is titrated and corrected to +.5 to phenolphthalein, to which is added 3.7 ml. of a 10-per cent solution of anhydrous sodium carbonate. For convenience it is flaked, sterilized, and stored in 200-ml. quantities. When ready to use the following ingredients are added to 200 ml. of agar as follows:

- (a) Dissolve two gm. chemically pure lactose in 25 to 30 ml. of distilled water, with the aid of gentle heat.
- (b) Dissolve .5 gm. of anhydrous sodium sulfite in 10 to 15 ml. of distilled water.
- (c) To the sulfite solution add one ml. of saturated solution of basic fuchsin in 95 per cent alcohol.

Add the fuchsin sulfite solution to the lactose solution and then add the whole to the agar. Pour plates at once, and after hardening dry for 15 minutes in the incubator.

Teague¹⁴³ has shown that a 10-per cent solution of sodium sulfite may be heated for 20 minutes at 15 pounds with practically no change. If this is then kept covered with a layer of petroleum, it may be kept for three weeks at room temperature.

Endo's Medium (After Levine¹⁴⁴). Levine states the method of preparation as follows:

Distilled water.....	1,000 ml.
Peptone (Difco).....	10 gm.
Dipotassium phosphate.....	2-5 gm.
Agar.....	15-30 gm.

139. Endo. 1904. Centbl. Bakt., Pt. 1, Orig., 35, 109.

140. Young and Marshall. 1925. J. Lab. and Clin. Med. 10, 532-535.

141. Kendall. 1911. J. Med. Res. 25, 95-99.

142. Hasseltine. 1918. U. S. Pub. Health Rpts. 32, 1878-1887.

143. Teague. 1918. J. Amer. Med. Assoc. 70, 454.

144. Levine. 1918. J. Infect. Dis. 23, 43-47.

These ingredients should be boiled until dissolved and the loss by evaporation made up with distilled water. No adjustment of the reaction is necessary; neither is filtration necessary if the medium is to be used for streaked cultures. Store in quantities of 100 ml. in Erlenmeyer flasks and when used add the following materials:

20 per cent lactose solution.....	1 gm. or 5.0 ml.
10 per cent alcoholic solution of basic fuchsin.....	0.5 ml.
Freshly prepared sodium sulfite solution.....	2.5 ml.

The theory of the reaction in Endo's medium has been explained in different ways. DeBord¹⁴⁵ quoted the investigations of Harding and Ostenberg,¹⁴⁶ who stated that the red color was due to the formation of aldehyde, and of Robinson and Rettger,¹⁴⁷ who believed that the reaction was due to acid and not aldehyde. DeBord attempted to clear up the question by comparing these reactions with those obtained when true Schiff's fuchsin aldehyde reagent¹⁴⁸ was used. DeBord concluded that Schiff's reagent would detect aldehyde formation in glucose and lactose media. Further, he found that the color change was produced with aldehydes only in the presence of acids. He considered the red color formed in Endo's medium by *Escherichia coli* to be due to the formation of both acid and aldehyde. Kahn¹⁴⁹ believed that the metallic sheen of typical *Escherichia coli* colonies on this medium is due to the evaporation of volatile substances produced in the metabolism of these bacteria.

Muller¹⁵⁰ concluded that the color change in Endo's agar medium was due to the formation of both acid and aldehyde. Barnewitz and Flecke¹⁵¹ showed that *Eberthella typhosa* produced small amounts of acid in both carbohydrate and carbohydrate-free media. The red color of Endo's agar they believed to be due to the formation of amino salts. They found that hydrochloric acid would not restore the color to basic fuchsin which had been decolorized with sodium sulfite but that lactic acid would.

Harris¹⁵² reported that the reaction of Endo's agar should be between pH 7.4 and 7.8. The use of Witte's peptone gave a less satisfactory medium than when three brands of American peptone were used. Harris found that the kind of dye also had influence on the quality of the medium. Basic fuchsin which contained a mixture of rosaniline and pararosaniline gave more consistent results than basic fuchsin containing chiefly rosaniline. Genung¹⁵³ also believed that the quality of peptone was partly responsible for varying results in the use of Endo's agar. One trouble in the use of this medium has been the diffusion of color or the substances causing the color change. It is interesting to note that she found that Witte's peptone gave less diffusion. One difficulty in the preparation of Endo's agar is that it

145. DeBord. 1918. J. Bact. 2, 309-314.

146. Harding and Ostenberg. 1912. J. Infect. Dis. 11, 109.

147. Robinson and Rettger. 1916. J. Med. Res. 29, 363.

148. According to DeBord, on authority of Mulliken, Schiff's fuchsin-aldehyde reagent is prepared by dissolving .2 gram basic fuchsin in 10 ml. freshly saturated solution of sulfur dioxide. After standing for some time, the solution should be a straw color. This is, then, made up to 200 ml. with distilled water and kept in a dark place.

149. Kahn. 1918. J. Bact. 3, 547-554.

150. Muller. 1924. Compt. Rend. Soc. Biol. 90, 653-655.

153. Genung. 1925. Abs. Bact. 9, 3.

should not be prepared and stored in large amounts. It is far better to be able to prepare the amount that is needed. This is possible with the availability of dehydrated Endo's agar as prepared by the Digestive Ferments Company.

Margolena and Hensen¹⁵⁴ confirmed Neuberg and Nord's theory that Endo's medium acts as a trapping agent for the intermediate product, acetaldehyde, which causes the Endo reaction. *Escherichia coli* was grown in a medium of a composition similar to Endo's medium with the exception that the sulfite fuchsin and agar were left out. When the fuchsin-sulfite mixture was added after 24, 36, and 48 hours, or after three and 10 days of incubation at 37°C., no reaction appeared. The substance that causes the reaction is formed only when the bacteria are grown in the presence of sulfite. When picric acid and ether are added to the red compound produced by the coliform organism in Endo's medium and the mixture is shaken, the color remains in the watery layer and thus the dye color that appears in the medium is not restored fuchsin, but a new substance. The work confirms LaGrange¹⁵⁵ who worked on this problem.

Brilliant Green Lactose Bile (Muer and Harris⁷⁸). The following medium was found to be especially valuable in preventing the development of anaerobic bacteria in the presumptive test in water analysis.

Distilled water.....	1,000.0 gm.
Ox gall (dried).....	50.0 gm.
Peptone.....	10.0 gm.
Lactose.....	10.0 gm.
Brilliant green.....	0.1 gm.

Distilled water is heated in a double boiler until the water in the outer container boils. Fifty grams of dried ox gall are added, with 10 grams of peptone, and dissolved. Boiling should be continued for one hour. After removing from the flame 10 grams of lactose are added. Filter and add 10 ml. of a one-per cent solution of brilliant green. Sterilize in tubes at 15 pounds for 15 minutes.

Dunham and Schoenlein¹⁵⁶ studied the medium proposed by Muer and Harris and reported that it did not show appreciable inhibition of *Escherichia coli*. They showed further that a medium containing two per cent of bile, one per cent of peptone, one per cent of lactose, and 1-75,000 brilliant green permitted more rapid development of *Escherichia coli* at pH 6.9 than the original brilliant green bile at its optimum pH. It is well to point out that some of the diverse conclusions which have been reached with brilliant green media may be due to the brand of dye used. Different brands and lots of dye vary greatly in efficiency. Rakieta and Rettger¹⁵⁷ and Berry and Daniels¹⁵⁸ made observations to this effect. A selective action of brilliant green has been discussed earlier in this chapter under liquid media (Stark and Curtis⁸⁰). Hook and Hitchner¹⁵⁹ also made such observations.

All cultures exhibited a greater dye tolerance when larger inocula were used. Aerobacter strains grew at a much higher dye concentration than

157. Rakieta and Rettger. 1927. J. Infect. Dis. 41, 93-110.

158. Berry and Daniels. 1928. Amer. J. Pub. Health 18, 883-892.

159. Hook and Hitchner. 1937. J. Bact. 33, 88.

the *Escherichia* strains. Within the genus the various cultures of both *Escherichia* and *Aerobacter* exhibited marked differences in dye tolerance, being more marked in representatives of the *Escherichia* group. Upon prolonged incubation many cultures produced visible growth at a dye concentration inhibitory during a shorter incubation period. A preliminary study with a few representative strains of *Escherichia coli* and *Aerobacter aerogenes* showed that when a 1:10 dilution of a 24-hour-old culture of the various strains was streaked on nutrient agar containing a 1:200,000 concentration of the dye, all *Escherichia* cultures showed no visible growth after 48 hours, while all *Aerobacter* strains grew rapidly. Further tests with 103 cultures, comprising 19 *Aerobacter* strains, 61 *Escherichia* strains, and 23 intermediates, differentiated by the M.R.-V.P., indol, citrate, and cellobiose tests, confirmed the results from the preliminary study with *Escherichia* and *Aerobacter* strains. The authors suggest the above procedure as a further means of differentiating the latter.

Lead Acetate Agar. Add .1 per cent of lead acetate to plain agar, tube, and sterilize. This medium has been useful for separating some of the paratyphoid bacteria. *Salmonella paratyphi* does not blacken this medium while *Salmonella schottmülleri* does. This medium is inoculated on the surface as well as by stabbing into the butt of the tube.

Kligler's¹⁶⁰ Lead Acetate Agar. Kligler proposed the following medium for differentiating members of the colon-typhoid group:

- (1) Meat infusion agar containing three-fourths per cent or one per cent agar (depending on the moisture content of the agar).
- (2) .1 per cent glucose.
- (3) .05 per cent of lead acetate.

The optimum reaction should be pH 7.2 to 7.6. The agar is prepared in the usual way except that three-fourths to one per cent of agar is used instead of the usual 1.5 per cent. This gives a semisolid medium which has several advantages. Gas production is readily observed by the diffusion of bubbles and breaking up of the medium.

The sugar and lead acetate are dissolved in water separately, sterilized, and added to the agar under aseptic conditions. It is necessary to cool the agar to about 60°C. (140°F.) before adding the lead acetate and to rotate the tube to insure uniform distribution. Kligler reported the following changes for the organisms indicated:

Eberthella typhosa—Browning along the line of growth.

Salmonella paratyphi—No browning, but gas formation.

Salmonella schottmülleri—Browning and gas formation.

Eberthella dysenteriae—Neither browning nor gas.

This has been confirmed by Jordan and Victorson,¹⁶¹ who used a medium containing 1.5 per cent of agar. Morishima¹⁶² also described a similar method. The differentiation is secured in about the same way as with Kligler's method.

Bailey and Lacy's¹⁶³ Modification of Kligler's Lead Acetate Medium. These investigators found phenol red to be a better indicator than Andrade's in Kligler's lead acetate medium. Their medium was prepared as follows:

Bacto beef extract.....	5 gm.
Peptone.....	10 gm.
Sodium chloride.....	5 gm.
Agar shreds.....	15 gm.
Tap water.....	1,000 ml.

160. Kligler. 1917. Amer. J. Pub. Health 7, 1042-1044.

161. Jordan and Victorson. 1917. J. Infect. Dis. 21, 544.

162. Morishima. 1918. J. Bact. 3, 19-22.

163. Bailey and Lacy. 1927. J. Bact. 13, 182-189.

The agar should be washed in running water and then heated in the required amount of water until dissolved. The other ingredients should then be added. Adjust the reaction to pH 7.4 and boil for a few minutes, adjust the reaction again, and allow to settle. The clear supernatant agar should then be decanted into another container and accurately divided into 100-ml. quantities. Sterilize at 10 pounds pressure for 20 minutes.

To each 100 ml. of medium add one gram of lactose, .1 gram of glucose, and .05 gram lead acetate after the medium has been melted and cooled to 50°C.(122°F.). Then add five ml. of a .02-per cent phenol red solution, tube, and sterilize at 15 pounds for 15 minutes.

Morishima's¹⁶² Medium for Differentiating Members of the Colon-Typhoid Group. Prepare meat infusion agar in the usual manner (Morishima cleared his medium with egg) and titrate to —.2 and —.4 with phenolphthalein as the indicator. Prepare a two-per cent solution of neutral lead acetate and heat for 30 minutes at 100°C.(212°F.) in a water bath. Five ml. of this solution should be added to 100 ml. of the melted agar and cooled to 60°C.(140°F.). Transfer this lead acetate agar to test tubes to a depth of about 1.5 ml. If the lead acetate is tubed while hot, the lead acetate settles to the bottom of the tube. This may be prevented by cooling the medium to 60 to 70°C.(140 to 158°F.) before tubing.

To 10 ml. of China blue (one per cent solution) add .4 ml. of normal sodium hydroxide and heat on the water bath for 10 minutes at 100°C.(212°F.). The color changes from blue to brown during the heating. One and one-fifth ml. of this decolorized China blue are added to 100 ml. of nutrient agar of reaction —.2 to —.4. One per cent of lactose and .1 per cent of glucose are added and the mixture is heated 10 minutes in the water bath at 100°C.(212°F.). This medium should be cooled to about 60°C. (140°F.) and should then be placed to about the same depth on the lead acetate. Incubate the tubes overnight and remove any contaminated ones in the morning.

Culture	Gas production	Bottom layer	Top layer
<i>Eberthella typhosa</i>	—	Black	Pale blue
<i>Salmonella paratyphi</i>	+	No change	Pale blue
<i>Salmonella schottmülleri</i>	+	Black	Colorless
<i>Salmonella enteriditis</i>	+	Black	Colorless
<i>Escherichia coli</i>	++	Black or no change	Deep blue

Methyl-Red-Voges-Proskauer Medium. *Standard Methods for the Examination of Water and Sewage* prescribed the following media:

(a) *Peptone Medium.* 1. To 800 ml. of distilled water add five gm. of Proteose-Peptone, Difco, or Witte's Peptone (other peptones should not be substituted), five gm. C. P. dextrose, and five gm. dipotassium hydrogen phosphate (K_2HPO_4). A dilute solution of the K_2HPO_4 should give a distinct pink with phenolphthalein.

2. Heat over steam, with occasional stirring, for 20 minutes.

3. Filter through folded filter paper, cool to 20°C.(68°F.), and dilute to 1,000 ml. with distilled water.

4. Distribute 10-ml. portions in sterilized test tubes.

5. Sterilize by the intermittent method for 20 minutes on three successive days.

(b) *Synthetic Medium.* 1. Dissolve seven gm. anhydrous disodium phosphate (Na_2HPO_4) or 8.8 gm. crystallized disodium phosphate ($Na_2HPO_4 \cdot 2H_2O$), two gm. potassium acid phthalate, one gm. aspartic acid, and four gm. dextrose in 800 ml. of warm distilled water.

2. Cool and dilute to one liter at room temperature.

3. Sterilize in autoclave for 15 minutes after the pressure has reached 15 pounds, provided the total time of exposure to heat is not more than one-half hour.

Bacto M.R.-V.P. medium, dehydrated, may be used if desired.

Hucker and Wall's¹⁶⁴ Medium for Nitrate Reduction and Ammonia Formation. The following medium for determining ammonia formation from organic sources was reported:

Peptone.....	4.0 per cent
Dextrose.....	0.2 per cent
Potassium phosphate (K_2HPO_4).....	0.5 per cent
Agar.....	15.0 gm.
Water.....	1,000.0 ml.

Add one ml. of a 10-per cent solution of phenol and one per cent (available chlorine) sodium hypochlorite solution to the surface of this medium. A blue color formed in one-half hour indicates ammonia formation.

Ammonia formation from inorganic sources may be determined with the following medium:

Water.....	1,000.0 ml.
Agar.....	15.0 gm.
Dextrose.....	10.0 gm.
Potassium nitrate.....	1.0 gm.
Calcium chloride.....	0.5 gm.
Potassium phosphate (K_2HPO_4).....	0.5 gm.

Other sources of nitrogen than potassium nitrate may be used if desired. To determine ammonia formation add two ml. of neutral formaldehyde or the test given with the medium mentioned above.

Eosin Brilliant-Green Agar (Teague and Clurman¹⁶⁵). This medium was devised for the rapid isolation of *Eberthella typhosa* from stools and was prepared in the following manner: 500 gm. of chopped beef are placed in one liter of distilled water and kept in the refrigerator overnight. The infusion is squeezed through cheesecloth, heated in the Arnold sterilizer and passed through filter paper. Witte's peptone (one per cent), chemically pure sodium chloride (.5 per cent) and agar (1.5 per cent) are added to the warm infusion, the peptone being rubbed into a paste in a little warm water. Then heat the flask of medium in the autoclave for 30 minutes at 120°C.(248°F.). Adjust the reaction to 1+ by adding 2N sodium hydroxide, cool to 55°C.(131°F.), clear and filter through cotton. Put into flasks in 100-ml. quantities and sterilize at 120°C.(248°F.) for 20 minutes.

When ready to use, melt the agar and add one per cent each of sucrose and lactose. To every 50 ml. of agar add one ml. of a three-per cent solution of yellowish eosin. From the stock solution of brilliant green in 50 per cent alcohol, a one-sixth-per cent solution is prepared in distilled water and one ml. of this is added to each 50 ml. of the agar. After the dyes are well distributed, pour into plates.

Eosin Methylene Blue Agar. The disadvantages in the use of Endo's Agar caused Holt-Harris and Teague¹⁶⁶ to study a new medium. They investigated the combinations of certain dyes with eosin. Eosin methylene blue agar was found to be a useful medium for differentiating *Escherichia coli* colonies from colonies of *Eberthella typhosa*. This differentiation was possible since the medium between the colonies was not colored by diffusion of acid from the colonies of *Escherichia coli*. The authors claimed the following advantages of eosin methylene blue over Endo's agar:

1. Earlier differentiation of *Escherichia coli* from other forms.
2. A greater percentage of colorless forms turn out to be *Eberthella typhosa*.
3. Complete inhibition of certain organisms which form small colonies on Endo's medium.
4. No change of color of plate on exposure to light.
5. Slight variations in reaction of medium do not affect it severely.

164. Hucker and Wall. 1922. J. Bact. 7, 515-518.

165. Teague and Clurman. 1916. J. Infect. Dis. 18, 647-652.

166. Holt-Harris and Teague. 1916. J. Infect. Dis. 18, 596-600.

Eosin-Methylene Blue Agar (Levine¹⁶⁶). This is a modification of Holt-Harris and Teague's medium and was found by Levine to allow a close separation between *Escherichia coli* and *Aerobacter aerogenes*. Levine described its preparation as follows:

Distilled water.....	1,000 ml.
Peptone (Difco).....	10 gm.
Dipotassium phosphate.....	2 gm.
Agar.....	15 gm.

Boil ingredients until dissolved and make up any loss by evaporation. Place measured quantities in flasks and sterilize at 15 pounds for 15 minutes. Just prior to use, add to each 100 ml. of the melted agar, prepared as above, the following constituents:

Sterile (20 per cent lactose).....	1 gm. or 5 ml.
Aqueous (2 per cent) eosin (yellowish) solution.....	2 ml.
Aqueous (2 per cent) methylene blue solution.....	2 ml.

Pour the medium into dishes, allow them to harden in the incubator, and inoculate in the usual way. There should be no adjustment of the reaction, and filtration of the medium is not necessary.

Levine¹⁶⁷ has also studied the medium in the differentiation of certain bacteriological indicators in water analysis and has shown the usefulness of this medium in sanitary work. The medium was also used in France and found to fulfill in many ways the ideal medium which will accurately differentiate between *Aerobacter aerogenes* and *Escherichia coli*.

Gilbert and Coleman¹⁶⁸ compared some of the more common differential media for isolating members of the colon typhoid group. Eosin brilliant green agar and brilliant green agar cannot be used alone, since they both inhibit *Shigella dysenteriae*. Eosin methylene blue agar was quite satisfactory. Kendall's modification of Endo's medium was not as satisfactory as the original formula or Robinson and Rettger's modification. Chesney¹⁶⁹ found that phenol red and brom-cresol-purple were good indicators in lactose agar for the isolation of members of the typhoid dysentery group from stools. Brom-cresol-purple, however, gave better differentiation. There is no reason why these indicators could not be used for isolation.

Eosin Methylene Blue Agar—Standard Methods for the Examination of Water and Sewage. Add 10 grams of Difco peptone, two grams of potassium phosphate (K_2HPO_4), and 15 grams of undried agar to 1,000 ml. of distilled water. Boil until all of the ingredients are dissolved and make up the loss by evaporation with distilled water. The reaction need not be adjusted.

Place measured quantities of the above medium (100 or 200 ml.) in flasks or bottles, plug, and sterilize in the autoclave. Use 15 pounds pressure for 15 minutes. Just before using, melt the stock agar and add the following ingredients to each 100 ml.:

Five ml. sterile 20-per cent lactose solution.

Two ml. two-per cent solution of yellowish eosin.

Two ml. .5-per cent solution of methylene blue.

Mix the medium thoroughly and pour into Petri dishes; allow to harden. Inoculate this medium by streaking on the surface. If desired, all of the ingredients may be added to the medium before sterilization. The color may disappear during sterilization but will return when the medium has cooled.

Skinner and Murray¹⁷⁰ stated that the addition of crystal violet in a concentration of 1 to 1,000,000 to the above-mentioned "Standard Methods" eosin methylene blue medium inhibited the development of spreading colonies. It was also stated that a

167. Levine. 1921. Iowa Eng. Expt. Sta. Bull. 62.

168. Gilbert and Coleman. 1922. Abs. Bact. 6, 35.

169. Chesney. 1922. J. Expt. Med. 35, 181-186.

170. Skinner and Murray. 1924. J. Infect. Dis. 34, 585-591.

sharper differentiation between *Escherichia coli* and *Aerobacter aerogenes* could be made. Panganiban and Schoble¹⁷¹ reported that eosin-methylene-blue agar gave a higher percentage of positive results than other media when examining stools for *Shigella dysenteriae*.

Differentiation of Aerobacter aerogenes and Escherichia coli on Eosin-Methylene Blue Agar (From Bull. 72, Digestive Ferments Company)

	<i>Escherichia coli</i> ¹	<i>Aerobacter aerogenes</i> ²
Size	Well-isolated colonies are 2-3 mm. in diameter.	Well-isolated colonies are larger than coli; usually 4-6 mm. in diameter or more.
Confluence	Neighboring colonies show little tendency to run together.	Neighboring colonies ² run together quickly.
Elevation	Colonies slightly raised; surface flat or slightly concave, rarely convex.	Colonies considerably raised and markedly convex; occasionally the center drops precipitately.
Appearance by transmitted light	Dark, almost black, centers which extend more than $\frac{3}{4}$ across the diameter of the colony; internal structure of central dark portion difficult to discern.	Centers deep brown; not as dark as <i>Escherichia coli</i> and smaller in proportion to the rest of the colony. Striated internal structure often observed in young colonies.
Appearance by reflected light	Colonies dark, button-like, often concentrically ringed with a greenish metallic sheen.	Much lighter than <i>Escherichia coli</i> , metallic sheen not observed except occasionally in depressed center when such is present.

¹ Two other types have been occasionally encountered: One resembles the type described, except that there is no metallic sheen, the colonies being wine colored. The other type of colony is somewhat larger (4 mm.), grows effusely, and has a marked crenated or irregular edge, the central portion showing a very distinct metallic sheen. These two varieties constitute about two or three per cent of the colonies observed.

² A small type of aerogenes colony, about the size of the colon colonies, which shows no tendency to coalesce, has been occasionally encountered.

Brom-Cresol Purple Lactose Agar (Torrey¹⁰⁸). This medium was devised by Torrey as a useful one for the study of the fecal flora. It was prepared as follows:

Five hundred grams of chopped beef heart (other meat material may be used) are boiled in one liter of water for 15 minutes over the free flame. Strain through cotton flannel and absorbent cotton as usual. Make up loss in filtrate with water and add 10 grams peptone and 15 grams flaked agar. Heat in Arnold until in solution. Adjust reaction to pH 7.4, and place in Arnold for 30 minutes. Readjust reaction, if necessary: Filter through absorbent cotton and add to filtrate 10 grams lactose and sufficient saturated alcoholic solution of brom-cresol-purple (generally about .75 ml.) to give the desired depth of color for a poured plate. Put in flask in 200-ml. amounts (sufficient for six plates) and autoclave at 15 pounds for 10 minutes.

Torrey stated that the Difco dehydrated medium could be used but the medium prepared from fresh meat gave a greater variety of bacterial types and had better differential value.

GELATIN MEDIA

Nutrient Gelatin. 1. Add three gm. of beef extract and five gm. of peptone to 1,000 ml. of distilled water, and add 100 gm. of gelatin dried for one-half hour at 105°C. (221°F.) before weighing.

2. Heat slowly on a steam bath to 60°C. (140°F.) until the gelatin is dissolved.

3. Make up lost weight, titrate, and if the reaction is not already between +.5 and +1, adjust to +1.

4. Filter through cloth and cotton until clear.
5. Distribute in test tubes, 10 ml. to each tube, or in larger containers if desired.
6. Sterilize in the autoclave at 15 pounds (120°C.[248°F.]) for 15 minutes after the pressure reaches 15 pounds.

Whey Gelatin. Add 10 per cent of gelatin to clarified whey. This medium is of value in studying certain members of the lactic acid bacteria group.

Thornton's Agar Medium. This medium was proposed by Thornton¹⁷² as especially used for preventing spreading colonies. It has the following composition:

Potassium phosphate (K_2HPO_4).....	10.0	gm.
Magnesium sulfate ($MgSO_4 + 7H_2O$).....	0.2	gm.
Calcium chloride ($CaCl_2$).....	0.1	gm.
Sodium chloride ($NaCl$).....	0.1	gm.
Ferric chloride ($FeCl_3$).....	0.002	gm.
Potassium nitrate (KNO_3).....	0.5	gm.
Asparagine.....	0.5	gm.
Mannitol.....	1.0	gm.
Agar.....	15.0	gm.
Water to.....	1,000.0	ml.

The phosphate, nitrate, and asparagine should be dissolved in distilled water and the magnesium sulfate, calcium chloride, sodium chloride, and ferric chloride added from the standard solutions in the order named. The agar is then added and dissolved at 100°C.(212°F.). The medium should then be filtered at 100°C.(212°F.) by being passed through a 1.2-inch layer of absorbent cotton—twice if necessary. Cool to 60°C.(140°F.) and adjust the reaction to pH 7.4 with brom-thymol-blue as the indicator. Tube and sterilize.

Litmus Gelatin. This may be prepared from lactose gelatin, the reaction of which must be neutral. Deposit one ml. of sterile litmus solution in the sterile Petri dish with the sample and pour in the melted gelatin. Shake the dish until the litmus is evenly distributed throughout. Incubate at 20°C.(68°F.). This medium is of much value in studying the bacteria in milk.

Raisin Gelatin (Besson¹⁷³). Make a decoction of raisins by grinding and stewing 50 to 100 grams of raisins in 1,000 grams of water for one hour. Filter and add 100 grams of gelatin and a pinch of sodium phosphate. Boil for two or three minutes. Neutralize and finish as usual.

Wort Gelatin. 1. Measure 900 ml. of beer wort in a sterile flask.

2. Weigh 100 grams gelatin (10 per cent) and add it to the wort in the flask.

3. Bubble live steam through for 10 minutes to dissolve the gelatin..

4. Cool to 60°C.(140°F.), clarify with egg.

5. Filter and tube.

Gelatin Agar (Besson). By mixing agar and gelatin a medium is obtained with a melting-point between that of either plain agar or plain gelatin.

Peptone broth.....	1,000	gm.
Gelatin.....	80	gm.
Agar.....	5	gm.

Or

Gelatin.....	50	gm.
Agar.....	8	gm.

Dissolve the gelatin in the broth, neutralize, and then add the agar. Sterilization must not be accomplished above 115°C.(239°F.). (See North's Agar Gelatin Medium.)

172. Thornton. 1922. Ann. Appl. Biol. 9, 241-274.

173. Besson. 1913. Practical Bacteriology, Microbiology and Serum Therapy, Longmans, Green & Co., New York, N. Y.

Jackson and Muer's⁷⁹ Liver Gelatin:

Beef liver.....	500 gm.
Peptone (Witte's).....	10 gm.
Dextrose.....	10 gm.
Potassium phosphate (K_2HPO_4).....	1 gm.
Water.....	1,000 ml.

1. Chop 500 grams of beef liver into small pieces and add 1,000 ml. of distilled water. Weigh the infusion and container.

2. Boil slowly for two hours in a double boiler, starting cold, and stirring it occasionally.

3. Make up the loss in weight by evaporation and strain through a wire strainer.

4. Cool the filtrate to 50°C.(122°F.). Add 10 per cent of sheet gelatin and stir a few minutes until dissolved.

5. Add one per cent of peptone, one per cent of dextrose, and one-tenth (.1) per cent of potassium phosphate.

6. Stir until the ingredients are dissolved, keeping the temperature below 50°C. (122°F.).

7. After warming this mixture in a double boiler and stirring it for a few minutes to dissolve the ingredients, titrate with N/20 sodium hydroxide, using phenolphthalein as an indicator, and neutralize with normal sodium hydroxide.

8. Boil vigorously for 30 minutes in a double boiler and for five minutes over a free flame, with constant stirring to prevent the caramelization of the dextrose.

9. Make up any loss in weight by evaporation and filter through cotton flannel and filter paper.

10. Tube and sterilize in an autoclave for 15 minutes at 120°C.(248°F.).

Worth's¹⁷⁴ Medium for Stock Cultures. The maintenance of stock cultures in as vigorous and unchanged condition as possible, is a very important matter in laboratories where many pure cultures have to be maintained. Worth worked out a medium which would do this for many bacteria. This medium is described by the author as follows:

Nutrient Gelatin:

Chopped beef.....	500 gm.
Water.....	1,000 ml.
Heated in a water bath 50 to 55°C. for one hour.	
Strained through bag cloth, volume restored.	
Peptone.....	10 gm.
Sodium chloride.....	5 gm.
Gelatin.....	100 gm.
Dissolved, filtered, adjusted to one per cent acid.	
Sterilize for 20 minutes at 110°C.(230°F.).	

Supplee's Medium for Streptococci. This medium was devised by Supplee for the preservation of cultures of streptococci. It was reported in a paper by Ayers and Johnson.¹⁷⁵

Meat infusion: (any desired amount)

Gelatin.....	2 per cent
Agar.....	2 per cent
Peptone.....	1 per cent
Nutrose (.5 per cent, or one per cent glucose)	
Reaction adjusted to neutral with phenolphthalein.	

174. Worth. 1919. J. Bact. 4, 603-608.

175. Ayers and Johnson. 1924. J. Bact. 9, 111-114.

Ayer and Johnson's¹⁷⁵ Medium for Stock Cultures. The following medium was proposed by Ayers and Johnson for the preservation of stock cultures of streptococci as well as other bacteria. The medium has the following composition:

Meat infusion:

Peptone (Parke, Davis and Co.).....	1.0	per cent
Gelatin (Difco).....	1.0	per cent
Casein (pure, Hammarsten).....	0.5	per cent
Glucose.....	0.05	per cent
Na ₂ HPO ₄ +2H ₂ O (Sorenson's phosphate).....	0.4	per cent
Sodium citrate.....	0.3	per cent
Agar.....	0.75	per cent

Ayers and Johnson suggested the following methods for the preparation of this medium:

Preparation of One Liter

A

Meat infusion broth.....	500 ml.
Peptone (Parke, Davis and Co.).....	10 gm.
Na ₂ HPO ₄ +2H ₂ O (Sorenson's phosphate).....	2 gm.

Heat until dissolved and then adjust to pH 7.8.

B

Distilled water.....	150 ml.
Casein (pure, Hammarsten's).....	5 gm.
Na ₂ HPO ₄ +2H ₂ O (Sorenson's phosphate).....	2 gm.

Heat until dissolved, add to A, and to the resulting mixture of A and B add 10 grams of gelatin (Difco).

C

Heat the mixture, A plus B, after adding the gelatin in the autoclave at 15 pounds for 10 minutes.

Add .5 gram of glucose.

The reaction should be pH 7.6.

Filter through paper.

D

Prepare 250 ml. of three-per cent agar. Filter through cotton and dissolve three grams of sodium citrate in the melted agar.

E

Mix agar and filtered solution from (C) and make up to 1,000 ml. by adding distilled water.

F

Tube and sterilize for 20 minutes at 15 pounds in the autoclave. After sterilizing allow tubes to cool slowly. If a slight precipitate has formed, it will settle or be absorbed in a short time; in either case the medium is not affected. The final pH is 7.5.

Reed and Orr's⁵⁹ Medium for Gelatin Liquefaction by Anaerobes. This medium was used by these authors for characterizing gas-gangrene anaerobes.

Gelatin.....	50 gm.
Bactopeptone.....	10 gm.
Sodium phosphate (Na ₂ HPO ₄).....	2 gm.
Dextrose.....	1 gm.
Sodium thioglycollate.....	1 gm.
Water.....	1,000 ml.

Browne's¹⁷⁶ Raw Cane Sugar Medium. This medium was used for studying the fungi which spoiled sugar. A 30-per cent solution of raw cane sugar of the ordinary 96°

176. Browne. 1918. J. Ind. Eng. Chem. 10, 178.

type is boiled with a little salt-free alumina cream, filtered, and diluted when cold to a concentration of 20° Brix. This stock solution may be sterilized and preserved. A solid medium is prepared by adding 15 grams of agar to 1,000 ml. of the medium.

Honey Agar (Fabian and Quinet¹⁷⁷). This medium was found to be necessary for isolation of spoilage organisms from fermented honey. Honey agar is made by mixing one part of honey and two parts of three-per cent nutrient agar. Adjust to pH 6.8 to 7.0; tube and sterilize.

Gee's Fish Media. Gee¹⁷⁸ used the following media in a study of bacteria which spoiled haddock. A fresh haddock was received from the fishing boats and the fresh muscle ground in a food grinder. To 500 grams of ground flesh, add 1,000 ml. of tap water and stir cold for one hour. Then heat the mixture so as to reach boiling in 20 minutes. After five minutes' boiling, pour the mixture through coarse filter paper. This gives a clear, faintly yellowish-green broth which should be autoclaved for 20 minutes at 15 pounds pressure in order to precipitate all of the remaining coagulable protein. After another filtration, the medium may be tubed and sterilized in the autoclave for 15 minutes at 15 pounds. This gives a clear culture fluid.

For solid media, such as fish agar, 1.5 per cent of agar is dissolved in the fish broth and filtered. The reaction of such media was found to be pH 6.6 to 6.8.

Spronck's¹⁷⁹ Peptone-Yeast Extract. To five liters of water add 1,000 gm. commercial yeast, not brewers' yeast. Boil for 20 minutes with stirring, pour into cylindrical vessels, and leave for 24 hours. Decant the cloudy liquid and add five gm. of sodium chloride and 10 gm. of peptone per liter. Neutralize exactly and then make alkaline to seven per cent with sodium hydroxide. Filter through Chardin paper and pour into flasks. Sterilize at 115°C.(239°F.).

Wine. Before sterilizing make neutral in the ordinary way.

Prune Decoction. Macerate 50 gm. of prunes in one liter of distilled water and allow to stand in the refrigerator until the next morning. Filter and tube for sterilization.

Pea-Flour Extract (Gordon et al.⁷⁴). Take 100 gm. of pea flour and add one liter of distilled water with 100 gm. of salt. Mix and steam for one-half hour, stirring constantly. Allow to settle and filter, then sterilize and label "saline pea extract." This pea-flour extract should preferably be freshly made for each batch of agar. This medium was especially designed to replace Witt's peptone.

Capaldi's Egg Medium. A few loopfuls of egg yolk are added to a tube of liquefied agar, previously cooled to 45 to 47°C.(113 to 116.6°F.).

Dorset's Egg Medium. Eggs are broken into a flask and the yolks broken with a needle or glass rod. The flask is shaken until the yolks and whites are thoroughly mixed. Foam formation should be avoided. Distribute in culture tubes and sterilize in a Koch inspissator or autoclave in the same manner as blood serum.

Egg-Meat Mixture (Rettger¹⁸⁰). A. One-half pound of lean chopped beef is stirred up in 250 ml. of water and, after neutralizing the meat acids with sodium carbonate, the mixture is heated in an Arnold sterilizer for 30 minutes, with occasional stirring. It is then set away in a cold place for several hours after which the fatty scum is removed.

B. The whites of three eggs are mixed with 250 ml. of water, and after neutralizing, the albumen is coagulated, with occasional stirring, by heating in the Arnold sterilizer for 30 minutes.

A and B are then mixed and introduced into a liter flask, along with 2.5 gm. (.5 per cent) of powdered calcium carbonate. The flask is plugged with cotton and sterilized for 30 minutes, at 110 to 112°C.(230 to 233.6°F.) (autoclave).

Holman's¹⁸¹ Cooked-Meat Medium. This medium was devised by Holman for studying anaerobic bacteria. It is prepared from fresh beef, freed from fat and other gross fibers. It is finely minced, ground in a mortar, and mixed with an equal part of water.

177. Fabian and Quinet. 1927. Mich. Agr. Expt. Sta. Tech. Bull. 92.

178. Gee. 1927. Studies Biol. Sta. of Canada 3, 349-363.

179. Spronck. 1898. Ann. Inst. Pasteur 12, 701-704.

180. Rettger. 1906. J. Biol. Chem. 2, 71-86.

181. Holman. 1919. J. Bact. 4, 149-155.

Then it is slowly heated to boiling, with constant stirring, to allow the soluble albumins to coagulate about the meat particles. This coagulated albumin serves in itself as a favorable medium for the anaerobes, as Tarozzi has shown. The emulsion of meat medium is then neutralized, or made slightly alkaline, using hot titration with phenolphthalein, tubed at least two inches high and autoclaved at 115°C. for at least an hour. Just before use the tubes are put in flowing steam and suddenly cooled. The seeding is done by pipette or needle.

Linden's¹⁸² Modification of Holman's Cooked-Meat Medium. According to Linden addition of 10 per cent tomato juice to Holman's cooked-meat medium gave satisfactory results for the isolation of the aciduric bacterial flora of acid canned foods undergoing decomposition. It is desirable to note also that a partial atmosphere of carbon dioxide in many instances appears to enhance the growth of the lactobacilli on solid culture media. While some of the culture media given above may serve to detect the presence of yeasts, the special media commonly used are acid in reaction and contain suitable carbohydrates.

Linden's¹⁸² Acid-Meat Medium for Aciduric Spoilage Bacteria. This medium was devised for detecting the presence of spoilage bacteria in acid foods, such as tomato products. The medium has the following composition:

Distilled water.....	1,000 ml.
Ground fresh lean beef.....	500 gm.
Proteose peptone.....	5 gm.
Sodium chloride, C. P.....	5 gm.
Dextrose, C. P.....	10 gm.

Infuse the beef in the water overnight in a refrigerator. Then heat in flowing steam or boil for 30 minutes. Strain through several layers of cheesecloth and squeeze out the liquid. Bring the infusion back to one liter. Add the peptone and heat in flowing steam or boil for 10 minutes. Filter and add the salt. Acidify with C. P. lactic acid to pH 4.7, add the dextrose, and filter.

Distribute the pressed-out beef into medium-size test tubes (150 x 20 mm.) about two grams in each tube, and add 10 ml. of the broth. Sterilize in the autoclave. The final reaction should be pH 4.8. Prior to using, boil the tubed medium for 10 minutes to expel oxygen, and cool.

Linden modified this medium by adding to each 1,000 ml. of broth as prepared above, 11 gm. of acetic acid and 12 gm. potassium citrate. This gives a final pH. of 4.5.

Cooked-Meat Medium (Torrey's¹⁰⁸ Modification of Robertson's Medium). Torrey described its preparation as follows:

Beef heart (fresh and finely minced).....	500 gm.
Peptone.....	10 gm.
Water.....	1 liter

This mixture, with the meat particles evenly suspended, is cooked in a double boiler with just enough heat to cause a slight simmering for about 10 minutes and the reaction adjusted to pH 7.2. The cooking is then continued for about one and one-half hours and the reaction readjusted, if necessary. The broth is decanted and the meat is then placed in test tubes, 16 to 17 mm. inside diameter, so that there is a column about five cm. high. After autoclaving these tubes and the broth in the flask at 15 pounds for 15 minutes, the latter is added to the meat tubes in five ml. amounts. The tubes are then placed in the Arnold on two successive days for 20 minutes. This method prevents the fluid being forced up into the cotton plug as is apt to occur if fluid and meat are placed together in tubes and then autoclaved.

Bengtson's¹⁸³ Coagulated Egg-White Medium. This consisted of beef infusion broth adjusted to a reaction of pH 7.6 with a piece of coagulated egg white in the bottom of the tube. This medium was used for studying the *Clostridium botulinum* group. Bengtson stated that the coagulated egg, if attacked, became smaller and the edges became rounded off.

182. Linden. 1936. Assoc. Off. Agr. Chem. J. 19, 440; 21 (1938), 454-457.

183. Bengtson. 1924. U. S. Public Health Service, Hyg. Lab. Bull. 139.

Ayers and Rupp's¹⁸⁴ Medium for the Colon-Aerogenes Group. In this medium lactose is the only source of carbon, and sodium ammonium phosphate the only source of nitrogen. The medium consists of two solutions:

- 1. Sodium ammonium phosphate .4 per cent, acid potassium phosphate .2 per cent, and lactose one per cent, dissolved in distilled water.
- 2. A filtered three-per cent solution of agar in distilled water.

Mix Solutions 1 and 2 in equal proportions while hot and put up in definite amounts of 100 ml. or more in flasks or bottles and then sterilize. The three-per cent agar solution is made up separately and kept in stock merely for convenience. Agar can be added directly to Solution 1 at the time of preparation if desired, using 1.5 per cent. A slight precipitate may appear upon sterilization but this does not interfere with the count and may not appear on the plate.

Jenkins¹⁸⁵ Tomato-Extract-Culture Medium. Cut the fruit into small pieces and steam for two hours, in water sufficient to cover the fruit. Filter and add 1.6 per cent of agar and heat for 30 minutes at 120°C.(248°F.). Adjust the reaction to —5 Eyre's scale with 40 per cent sodium hydroxide. Filter to remove the precipitate and again adjust the reaction. Tube while hot.

Ox-Bile Medium. Dissolve one per cent lactose and one per cent peptone in fresh ox bile, filter, and place in fermentation tubes. Sterilize in an Arnold on three successive days.

Decoction of Dried Fruits. 1. Macerate 50 to 100 gm. of dried fruit in a liter of water for several hours, then stew them in the water.

- 2. Pass through a coarse sieve.
- 3. Boil. Filter.
- 4. Tube and sterilize at 115°C.(239°F.).

The liquid is slightly acid and is useful for cultivating molds. Otherwise make neutral.

Barsiekow's Medium. Prepare and sterilize separately the two following solutions:

A. Sodium chloride.....	0.5 gm.
Nutrose.....	1.0 gm.
Water.....	75.0 gm.
B. Water.....	25.0 gm.
Litmus.....	To give blue color
Sugar (the one desired).....	1.0 gm.

Add sufficient litmus to give an amethyst color. After cooling mix and distribute in tubes.

Bread. Soak some slices of white bread in distilled water and sterilize at 115°C. (239°F).

Crumble some bread and allow to dry. Grind when dry and put in Petri dishes or Erlenmeyer flask and add water to moisten (about 2½ parts of water to one part of bread by weight).

Sterilize at 115°C.(239°F.) for 20 minutes.

Medium for Acetic-Acid Bacteria. The following medium was reported by Janke¹⁸⁶ as especially suitable for vinegar bacteria:

Potassium diphosphate.....	0.4 gm.
Ammonium diphosphate.....	1.0 gm.
Magnesium sulfate.....	0.4 gm.
Glycerol.....	5.0 ml.
Succinic acid.....	1.0 gm.
Alcohol.....	3.0 pct. by vol.
Water.....	1,000.0 ml.

184. Ayers and Rupp. 1918. J. Bact. 3, 433-436.
185. Jenkins. 1923. J. Path. and Bact. 26, 116-118.
186. Janke. 1921. Centbl. Bakt., Pt. 2, 53, 81.

Fowler and Subramaniam's¹⁸⁷ Medium for Acetic-Acid Bacteria. Alcohol, four per cent by volume; acetic acid, two per cent (vinegar containing acetic acid to this amount); phosphates of calcium, magnesium, and potassium, .05 per cent; yeast water, 10 ml., prepared by boiling seven per cent by weight of dry yeast with water, and filtering until quite bright; the whole being made up with sterile water to 100 ml.

Medium for Acetic-Acid Bacteria. Prepare beer wort or malt medium with four per cent of alcohol and about .3 per cent of acetic acid or sterile vinegar. Incubate at about 25.6°C.(78°F.).

POTATO AND STARCH MEDIA

Potato Gelatin (Goadby). Add 100 gm. of gelatin to one liter of glycerol potato broth. Boil, adjust the reaction, filter, and sterilize.

Glycerol Potato Broth. Wash, peel, and grind 1,000 gm. of potato. Soak this in a liter of water for 24 hours. After filtering add three to five per cent of glycerol and tube for sterilization.

Potato Agar (McBeth¹⁸⁸). Pare, steam, and mash a quantity of potatoes. To 100 gm. of mashed potato add 800 ml. of tap water and steam for one-half hour, filter through cotton.

Potato solution.....	500 ml.
Agar.....	15 gm.
Nutrient solution (same as for cellulose agar).....	500 ml.

Starch Agar. Make one liter of ordinary peptone agar. Add to this a two-per cent paste of potato starch. This should be added at as low a temperature as possible to the neutral agar.

To use, pour plates with the sterile tubed starch agar and streak with the culture. After incubation for five days, pour over weak solution of Lugol's iodine.

Starch Agar ((Vedder¹⁸⁹). Prepare a liter of beef infusion in the usual way. Meat extract does not give as good results. To this add 1.5 per cent of agar. No peptone or salt should be added. Cook and clarify the medium and add 10 grams of cornstarch to each liter. The starch is best rubbed up in a mortar in a little agar. One per cent of starch gives the best results. Tube and sterilize in the usual manner. This medium is especially valuable in the growth of gonococci.

Elsner's Potato Medium. 1. Peel and grate 500 grams of potato.

2. Grind up and soak in distilled water for 12 hours.

3. Strain and allow to stand. Filter to clear.

4. Make up to one liter and dissolve 15 per cent of gelatin.

5. Adjust reaction to acid and sterilize.

Potato Infusion. Wash and grind up a few potatoes. To each 30 gm. of potato, add a liter of distilled water and allow to stand in the refrigerator overnight. In the morning, filter and boil the filtrate. Filter again if necessary and tube for sterilization. If the infusion is too acid, adjust the reaction as usual.

Potato Mash. Clean and cut a large potato into slices. Boil until soft and grate or press through a ricer. Distribute this in layers in Petri dishes and sterilize at 120°C. (248°F.) for 20 minutes. The slices may be placed in the Petri dishes without mashing if desired.

Starch Jelly (Smith¹⁹⁰). To 10 ml. of Uschinsky's solution add one gm. of clean aseptic starch. Rub this up in the slanted fluid. Plug the tubes tightly and place in an inspissator or Arnold in the slanted condition. Heat for two hours on five successive days at 85 to 93°C.(185 to 199.4°F.). If water is lost, this must be made up by the addition of distilled water.

Potato Agar (Thomas). The potatoes are carefully washed, pared, sliced, then slowly heated for two hours in approximately two volumes of water. At the close of the heating the water is allowed to boil. The whole is then filtered through cloth, water

187. Fowler and Subramaniam. 1923. Indian Inst. Sci. J. 6, 147-172.

188. McBeth. 1913. U. S. Dept. Agr., Bur. Anim. Indus. Bull. 266.

189. Vedder. 1915. J. Infect. Dis. 16, 385-388.

190. Smith. 1898. Centbl. Bakt., Pt. 2, 5, 102.

being added to make up the loss of any evaporation. After filtering, one per cent shredded agar is added to this filtrate. It may then be heated in an autoclave for 30 minutes at 15 pounds, after which it may be tubed or filtered, if desired, before tubing.

Starch Agar (McBeth¹⁹⁸). To 800 ml. of boiling water add 10 gm. of potato starch suspended in a little cold water. Concentrate by boiling to 500 ml. This breaks up the starch grains and should give a nearly transparent starch solution.

Starch solution.....	500 ml.
Agar.....	10 gm.
Nutrient solution (same as for cellulose).....	500 ml.

SYNTHETIC MEDIA

Such media are usually prepared from pure chemical compounds. Uschinsky's synthetic medium is a good example and has been widely used. Hulton-Fraenkel¹⁹¹ proposed several such media.

Koser's¹⁹² Citrate Solution. Koser reported further work on his citrate solution for differentiating *Escherichia coli* of intestinal origin from non-fecal *Aerobacter aerogenes*. The former were found to be unable to utilize the carbon in the citrate molecule and thus does not grow while the latter organism, *Aerobacter aerogenes*, grows well. Koser reported two possible media as follows:

Medium 1

Distilled water.....	1,000.0 ml.
Sodium chloride (NaCl).....	5.0 gm.
Magnesium sulfate (MgSO ₄).....	0.2 gm.
Ammonium phosphate (NH ₄) H ₂ PO ₄	1.0 gm.
Potassium phosphate (K ₂ HPO ₄).....	1.0 gm.
(Sodium citrate: 5½ H ₂ O.....)	2.77 gm.) 2.0 gm.

Medium 2

Distilled water.....	1,000.0 ml.
Sodium ammonium phosphate (microcosmic salt Na[NH ₄]HPO ₄ +4H ₂ O).....	1.5 gm.
Potassium phosphate (KH ₂ PO ₄).....	1.0 gm.
Magnesium sulfate (MgSO ₄).....	0.2 gm.

Sodium or potassium citrate as given in *Medium 1* above.

After dissolving the various salts in sterile distilled water, add 20 grams of clean, dry agar and sterilize the medium at 15 pounds for 15 minutes. After adjusting the reaction to pH 6.8, add the indicator and distribute into tubes. Simmons⁸³ prepared a solid medium by adding agar to Koser's citrate solution. Its preparation has been described above.

Doloff's¹⁹³ Synthetic Medium. This simplified medium was devised for propagating *Escherichia coli*.

Ammonium tartrate, recrystallized.....	5 gm.
Lactose.....	5 gm.
Ammonium phosphate (NH ₄) ₂ HPO ₄	0.01-0.02 gm.
Water.....	1,000 ml.

The reaction of this medium after sterilization is between pH 5.0 to 5.2.

BLOOD AND BLOOD SERUM MEDIA

Blood Serum. Beef blood should be collected at the abattoir in clean containers and placed in the refrigerator until a clot has formed. The clear serum should then be decanted, or better, siphoned off into a sterile flask. For the preparation of Loeffler's

191. Hulton-Fraenkel. 1919. J. Infect. Dis. 24, 9-16; 19-21.
192. Koser. 1924. J. Bact. 9, 59-77.
193. Doloff. 1926. Science 64, 254.

blood serum, one part of glucose broth is mixed with three parts of the serum. This is then distributed into test tubes (or other containers) and placed in the inspissator in a slanted position. Small tin ointment boxes make good containers when the blood serum is to be used for routine diphtheria examinations. After coagulation has been accomplished, the boiled serum should be sterilized in the autoclave at a temperature of about 112°C. (233.6°F.). If desired, intermittent heating in the Arnold may be used.

Blood Agar for Streptococci (Becker¹⁹⁴). Standard agar used in water analysis is placed in quantities of 40 to 100 ml. in flasks. These are heated until the agar is melted, and then cooled to 45 or 50°C. (113 or 122°F.). One milliliter of defibrinated human blood is added for each six ml. of the agar base and the whole is thoroughly shaken. Approximately seven ml. are used for each plate. Surface streaks are made and observations made after 24 hours at 27°C. (80.6°F.). Isolated colonies only should be studied.

MILK MEDIA

Sterile milk is a good medium for the propagation of most bacteria. It has been modified in different ways to give many different media.

Kulp's¹⁹⁵ Casein-Digest Medium. This medium was prepared in 1923 by Kulp for the study of *Lactobacillus acidophilus* and *Lactobacillus bulgaricus*. Kulp described the method of preparation as follows: One hundred grams of casein are dissolved in one liter of one-per cent sodium carbonate; one and one-half grams of Fairchild's trypsin (powder) are added with a little chloroform for a preservative. This mixture is then incubated for 24 to 48 hours at 37 to 40°C. (98.6 to 104°F.); it should then be heated in a double boiler to drive off the chloroform and made slightly acid with 15 per cent hydrochloric acid. Finally it is boiled for a few minutes and filtered. One hundred ml. of the digest representing 10 grams of the original casein, plus three grams of commercial meat extract are used as the base for each liter of medium desired. A digest of "Klim" was also prepared and gave good results. A casein digest broth was also found to be a good medium for indole formation.

Safford and Stark's¹⁹⁶ Skim-Milk Agar. The composition was as follows:

Fresh raw skim milk.....	2.0 per cent
Bacto peptone.....	0.5 per cent
Bacto beef extract.....	0.1 per cent
Glucose.....	0.1 per cent
Agar.....	1.5 per cent

Fresh skimmed milk was used, for it was believed a better medium was secured with it than if powdered milk were used. The raw skimmed milk was added to the medium just prior to sterilization.

Hydrolyzed Casein Medium (Cannon¹⁹⁷). Zipfel proposed the addition of tryptophane to a synthetic medium for the determination of indol formation. Cannon realized the high cost of tryptophane and suggested the use of a hydrolyzed casein which is prepared as follows: Ten grams of casein are hydrolyzed by 200 ml. of 10-per cent sulfuric acid. The mixture is kept on the water bath for 24 hours after which it is neutralized by saturated barium hydroxide. This will precipitate the sulfate. Evaporate the resulting solution until the amino acids crystallize. Half of the preparation is then dissolved in 500 ml. of Zipfel's synthetic medium, which has the following composition:

Asparagin.....	5.0 gm.
Ammonium lactate.....	5.0 gm.
Potassium acid phosphate.....	2.0 gm.
Magnesium sulfate.....	0.2 gm.
Distilled water.....	1,000.0 gm.

194. Becker. 1916. J. Infect. Dis. 19, 754-759.

195. Kulp. 1923. Abs. Bact. 7.

196. Safford and Stark. 1935. J. Dairy Sci. 18, 539.

197. Cannon. 1916. J. Bact. 1, 535-536.

Sherman and Albus'¹⁹⁸ Medium for Cultivating Lactobacilli. The medium proposed had the following composition:

Fermentable carbohydrate.....	1.0 per cent
Peptone.....	1.0 per cent
Dried yeast.....	1.0 per cent
Butter fat.....	1.0 per cent
Agar.....	0.2 per cent
Reaction.....	pH 6.5-7.0

The agar is not absolutely essential but favors the growth of some cultures.

Casein Agar (Ayers¹⁹⁹). Preparation of one liter.

Casein solution:

300 ml. distilled water.

10 grams casein (Eimer & Amend C. P. casein prepared according to Hammarsten).

7 ml. normal sodium hydroxide.

Agar solution:

500 ml. distilled water.

10 grams agar.

After dissolving casein, make up to 500 milliliters.

To 300 ml. of water (distilled) add:

10 grams casein (Eimer & Amend C. P. casein prepared according to Hammarsten).

7 ml. normal sodium hydroxide.

Dissolve casein by heating to boiling. It is desirable to let this solution stand for several hours to get a perfect solution. This is not necessary, however. Make up volume to 500 ml. and bring the reaction of the solution to between +0.1 and +0.2 Fuller's scale. Do not allow solution to become alkaline to phenolphthalein or over +0.2. If the casein is weighed accurately and the normal solution is accurate, the reaction will be about +0.2.

The agar solution is prepared by dissolving 10 grams agar in 500 ml. of water. Both casein and agar solutions should be filtered, then mixed. Tube and sterilize in autoclave under pressure for 20 minutes; then cool the tubes quickly in cold water or ice water. The final reaction of the medium will be about +0.1 Fuller's scale. If the medium is alkaline the bacterial growth will be restricted. If the medium is more than +0.1 some of the casein may be precipitated during sterilization. The casein agar should be clear and almost colorless when poured in a Petri dish. Sometimes the casein will be slightly precipitated during sterilization or the cooling, but it is of no consequence since on pouring into plates the precipitate, on account of its finely divided condition, becomes invisible.

Whey Agar. Add a few drops of acetic acid to boiling milk until the casein is precipitated. Neutralize, or bring to one per cent +. Dissolve one per cent peptone, two per cent dextrose, and 1.5 per cent agar. Filter, tube, and sterilize.

Plain Milk. This may be made from fresh skimmed milk or from skimmed milk powder.

Desiccated milk..... 100 gm.

Distilled water..... 1,000 gm.

The milk powder should be added to about 200 ml. of the distilled water and thoroughly mixed. Beating with an egg beater often serves this purpose. It should then be made up to a liter. Sterilize in an Arnold.

Litmus Milk. Add sterile litmus or azolitmin to plain skimmed milk until the color is a distinct lavender. Tube in any of the laboratory apparatus and sterilize.

198. Sherman and Albus. 1922. Abs. Bact. 6, 17.

199. Ayers. 1913. U. S. Dept. Agr., Bur. Anim. Indus., Ann. Rpt. 1913, 225-235.

200. Hamilton. 1921. J. Bact. 6, 43-44.

Litmus Milk Powder. Hamilton¹⁹⁷ prepared litmus milk powder as follows: Litmus cubes were extracted with boiling distilled water and evaporated to a thin paste after decantation. This was then treated with an excess of acetic acid, evaporated to dryness, treated with 95 per cent alcohol, filtered, dissolved in water, and evaporated. One part of this indicator was added to 52.7 parts of dried skimmed milk powder. One part of the litmus milk powder was dissolved in 9.5 parts of water to make litmus milk.

Clark and Lubs'²⁰¹ Brom-Cresol-Purple Milk. They suggested brom-cresol-purple instead of litmus in milk cultures. They compared the two indicators and found that brom-cresol-purple was just as delicate as litmus and had the same adaptability. In some tests and culture media litmus is decolorized and does not function as an indicator while brom-cresol-purple acted as a true indicator of hydrogen-ion concentration. During sterilization litmus undergoes a temporary decolorization while brom-cresol-purple does not. The indicator may be added to the milk to give the depth of color desired. Baker²⁰² substituted brom-thymol-blue for litmus in culture media.

Bronfenbrenner, Davis, and Morishima's²⁰² Milk Media. These investigators used fresh milk and milk whey for culture fluids.

Milk Medium. Heat fresh milk in the Arnold sterilizer for 15 minutes and then place on ice for eight to 12 hours; separate the cream. Dilute one part of milk with three parts of water. Add an indicator (mixture of China blue and rosolic acid) at the rate of 2.5 ml. per 100 ml. of diluted milk; boil for five minutes; if too acid, adjust the reaction until a pale gray color is secured. Distribute in sterile tubes with inverted vials and autoclave at 15 pounds for 10 minutes.

Milk-Whey Medium. Siphon the milk from under the cream and bring it to a boil; then add 2.5 ml. of a 10-per cent manganese chloride solution to each 100 ml. of medium. Cool as soon as the clot forms and filter through a single layer of cloth. Adjust to neutrality and dilute the filtrate with double its volume of distilled water. Add one ml. of cresol-red indicator for each 100 ml. of medium. Place in sterile culture tubes having inverted vials and autoclave for 10 minutes at 15 pounds.

Transparent milk has been proposed by Brown and Howe²⁰⁴ as a useful culture medium. They prepared it by diluting one part of skimmed milk with two parts of distilled water and then adding .4 per cent of sodium citrate. It may be filtered after an hour or so, although this is said to be unnecessary if the milk is allowed to stand long enough. To avoid caramelization of the sugar the reaction should be adjusted to pH 6.8. Oxalated milk was also prepared in the same manner.

Litmus Milk From Skimmed-Milk Powder (Vierling²⁰⁵). Dissolve 30 gm. of skimmed milk in 200 ml. distilled water over a warm water bath; add four ml. of an 18-per cent solution of potassium chloride and heat for 40 minutes on a steam bath for precipitation of casein. Remove excess potassium chloride by adding two ml. normal sodium hydroxide and heat for 25 minutes. Filter and make up to 500 ml. by addition of 150 ml. of distilled water and 150 ml. physiological salt solution, then add .02 to .03 gm. of peptone. After 30 minutes' sterilization add 20 to 30 ml. of sterile litmus solution. Standardize by N/10 sodium hydroxide or lactic acid.

Hunter's²⁰⁶ Medium for *Lactobacillus acidophilus*. Hunter found the following medium to be very useful for propagation of microorganisms of the aciduric group:

Casein.....	15.0 gm.
Peptone.....	15.0 gm.
Beef extract.....	3.0 gm.
Trypsin.....	1.5 gm.
Water.....	1,000.0 ml.

This mixture was made slightly alkaline; chloroform was added to preserve it during incubation at 37°C.(98.6°F.) for 48 hours. After removal from the incubator the

202. Baker. 1922. J. Bact. 7, 301-305.

203. Bronfenbrenner, Davis, and Morishima. 1919. J. Med. Res. 39, 345.

204. Brown and Howe. 1922. J. Bact. 7, 511-514.

205. Vierling. 1922. Centbl. Bakt., Pt. 1, Orig. 88, 93-94.

206. Hunter. 1924. Abs. Bact. 8, 8.

medium was boiled to drive off the chloroform. The reaction was adjusted to pH 7.0 and 15 grams of lactose and 50 ml. of a two-per cent solution of sodium oleate were added.

Litmus Whey (Petruschky). Fresh milk is slightly warmed and treated with dilute hydrochloric acid to precipitate the casein. This is filtered off and dilute sodium carbonate added to the filtrate to neutrality. This is then steamed for two hours to precipitate any casein which is changed to acid albumin by the dilute hydrochloric acid. After filtration a clear neutral solution should be the result. This is colored with litmus, tubed, and sterilized. After growth the amount of acid may be determined by standard reagents.

Rice Milk (Besson¹⁷³):

Milk.....	150 gm.
Peptone broth.....	50 gm.
Powdered rice.....	100 gm.

Distribute the mixture in Petri dishes one to two cm. deep. Heat to 115°C.(239°F.) for 20 minutes. The mixture solidifies and forms an opaque layer.

Dialyzed Milk. Dialyzed milk may be prepared by the addition of 10 ml. of hydrogen peroxide to 500 ml. of milk. Two hours later hydrogen peroxide should be added again, and after four to five hours the whole is dialyzed. The sugar content is reduced 50 per cent and the normal quantities of fat and proteins are preserved. The milk is diluted one-fifth.

Milk Agar (Hastings²⁰⁷). This medium is prepared by adding to ordinary nutrient agar, which has been melted and cooled to 50°C.(122°F.), 10 per cent sterile skimmed milk. If the milk is added to the agar while hot, the casein will be precipitated in coarse flocculent masses. The medium is poured into sterile Petri dishes and after hardening is streaked with the cultures. After incubation, if proteolytic action is present, there will be a clear zone about the streak which will not change when treated with dilute acids. This distinguishes the acid formers from the proteolytic bacteria.

Casein-Digest Medium. This medium was reported by Townsend²⁰⁸ as having been adapted by Sommer for the production of spores of *Clostridium botulinum*.

Make a one per cent sodium carbonate solution equal in volume to the amount of medium desired. To this add 10 per cent casein and heat in a water bath or double boiler until the casein is well in suspension. Cool to about 40°C.(104°F.), and add two-thirds gm. of pancreatin (or trypsin) per liter. Distribute in flasks for digestion, using chloroform or toluene as preservative. Incubate overnight (approximately 18 hours). Boil off the preservative and acidify strongly with 5N hydrochloric acid (down to pH 5.6 to 5.2). Filter. Neutralize with 5N sodium hydroxide, and add .5 per cent Liebig's beef extract and .5 per cent dibasic sodium phosphate. Make up to volume and check the reaction to pH 7.2 to 7.6. Sterilize at 15 pounds pressure for 45 minutes. Five-tenths per cent glucose is added before sterilization for some organisms.

Whittaker's²⁰⁹ Synthetic-Milk Medium. Whittaker reported the following method for making artificial milk:

"Fifteen grams of pure caseinogen are dissolved in 100 ml. of a one-per cent solution of sodium hydroxide in distilled water. Eighteen to 24 hours may be required for a complete solution. After the caseinogen is dissolved the solution is diluted to about 900 ml. with distilled water. Ten grams of lactose and .1 gram of calcium chloride are added and the solution made up to 1,000 ml. with distilled water. It is then neutralized and made +.3 with N/1 hydrochloric acid, using phenolphthalein as an indicator. This medium is sterilized in an autoclave at 107°C.(224.6°F.) for 20 minutes. The finished product should be a clear, transparent solution. When the medium has a reaction of +.3 about 24 hours are usually required for coagulation with an active strain of *Escherichia coli*. When the reaction is neutral a somewhat longer time may be required

207. Hastings. 1904. Centbl. Bakt., Pt. 2, 12, 590-592.

209. Whittaker. 1912. Amer. J. Pub. Health 2, 162.

to produce similar results. This medium has been thoroughly tested on the routine test for *Escherichia coli* and apparently meets all requirements."

YEAST MEDIA

Fred, Peterson, and Davenport's²¹⁰ Yeast-Water Medium. This medium was prepared in 1920 as follows:

Four hundred and fifty grams of pressed yeast were steamed three to four hours with 4.5 ml. of tap water with occasional stirring. This infusion was allowed to stand undisturbed until a heavy deposit of yeast cells and other suspended matter had settled to the bottom of the vessel. The portion above this deposit was poured off and neutralized in liter flasks. The flasks were allowed to stand one to two weeks, when the supernatant liquid was siphoned off and used without clearing or filtering.

Dienert and Guillerd's²¹¹ Autolyzed Yeast Medium. This medium, devised for use in place of more expensive peptone media, is prepared as follows:

Five hundred grams of pressed yeast are heated to 50°C. (122°F.), which temperature is favorable for the action of the endotryptase but not for the action of bacteria. The liquefaction is complete in less than 24 hours, yielding about 400 ml. of the autolyzed fluid. This is diluted to 2,000 ml. with water and heated to 100°C. (212°F.) for 30 minutes. It is then neutralized, filtered, and finally made up to 7,500 ml.

Eberson's²¹² Yeast Media. This medium was prepared for culturing delicate organisms which grew scantily on the usual media. The meningococcus is a good example of such a bacterium. Eberson prepared this medium as follows:

Thoroughly macerate 10 grams of baker's or brewer's yeast in 100 ml. of water for 20 minutes and then steam for two hours, not exceeding a temperature of 100°C. (212°F.). Filter twice through filter paper. A clearer medium may be secured by clarifying with liquor ferri oxychlorati before filtering. By the use of glass wool, chemical clarification may be dispensed with and the absorption by filter paper of "accessory food products" may be prevented. Prepare a 2.5-per cent agar having a pH of 7.4 with or without peptone or salt. To each 60 ml. of the agar add 40 ml. of the yeast decoction. Sterilize in the autoclave for 20 to 30 minutes and slant. A semisolid yeast agar (.5 per cent) is prepared similarly and the culture tubes inoculated with a series of stabs. Indications are that this culture medium will prolong the viability far beyond the periods observed for the solid media.

Burky²¹³ found this medium a very suitable one for maintaining cultures of bacteria which are usually grown with difficulty.

Johanson and Broadhurst's²¹⁴ Yeast Medium. This medium was proposed as a substitute for meat-extract media. It contained the following ingredients:

Water.....	1,000 ml.
Peptone.....	10 gm.
Salt.....	5 gm.
Yeast (Fleischmann's).....	2 cakes

It should be pointed out that the addition of the cakes of yeasts introduced considerable starch also.

Kligler's Yeast Medium. Kligler²¹⁵ prepared a medium which may be used in place of the commoner meat media. He has described its preparation as follows:

"Two hundred grams of drained or centrifuged brewer's yeast are suspended in a liter of water, two grams of NaH_2PO_4 are added as buffer, and the reaction adjusted by the addition of N/NaOH to pH 6.1. Then five ml. of chloroform are added and the mixture is thoroughly shaken and incubated at 37°C. for two days. It is necessary to shake the flask occasionally during the incubation to maintain sterility. At the end of the incubation period, the reaction is brought to pH 7.4 and the autolysate heated in a

215. Kligler. 1919. J. Bact. 4, 183-188.

water bath or in the Arnold for 30 minutes. It is then filtered through paper, tubed, and autoclaved. Agar is prepared by adding 15 grams of agar directly to one liter of the unfiltered autolysate and stirring thoroughly to immerse or soften the agar shreds or powder. This mixture is then heated over the free flame or in the autoclave until the agar is completely dissolved. The reaction is then adjusted to pH 7.4, the mixture is heated on a water bath or in an Arnold for half an hour, and the partially clear supernatant fluid is decanted to an Erlenmeyer flask or other vessel. The agar is then cooled and whole egg added to clear. The medium is finally steamed in the Arnold for one-half to three-quarters of an hour, filtered, tubed, and autoclaved."

Neill, Sugg, Richardson, and Fleming's²¹⁶ Yeast-Culture Media. Neill and his colleagues found the yeast media, preparation of which is described below, satisfactory in all routine bacteriological procedures for which meat infusion peptone media are used. They described the preparation of the medium as follows:

I. PREPARATION OF "5% YEAST" BROTH

The medium, found satisfactory as a routine substitute for meat-infusion-peptone broth, was prepared by the following steps. For convenience, the amounts of material are expressed in terms of 10-liter lots of medium.

1. Infusion of the dried yeast. Warm 10 liters distilled water to 40°C., add 500 grams Fleischmann's dried yeast to the water and infuse at 40°C. for 30 minutes; raise temperature to 50°C. and continue the infusion for 90 minutes.

2. Preliminary adjustment of pH of the infusion before boiling. Add eight per cent (2.0N) sodium hydroxide to the infusion until phenol red gives a faint pink when added to samples of the turbid yeast suspension (about 40 ml. 2.0N NaOH are usually required). Add 30 grams $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ previously dissolved in 100 to 200 ml. of warm water.

3. Boiling and preliminary filtration of yeast infusion. Raise temperature to boiling; stirring is necessary when the temperature approaches the boiling point. Boil for one to three minutes. Filter through paper.

4. Adjustment of volume. Add water to compensate for loss due to evaporation and filtration, until volume is 9.5 liters.

5. Final adjustment of pH. The broth is perfectly clear after filtration in Step 3, and colorimetric tests always show the pH to have dropped below 7.0. Adjust by addition of sodium hydroxide until pH is from 7.2 to 7.4. Add 150 grams $\text{Na}_2\text{HPO}_4 \cdot 12\text{H}_2\text{O}$ previously dissolved in 500 ml. warm water. The addition of this phosphate usually raises the pH to about 8.0 with media prepared from most lots of the dried yeast. If a final pH of 7.8 is desired, the broth should be readjusted by addition of alkali, or acid, if it is not pH 8.0 after addition of the phosphate at this stage. (We prefer to adjust the pH with NaOH added in the order described to a point sufficient to enable the last addition of phosphate to raise the pH to 8.0. This point [usually pH 7.2 to 7.4] varies to some extent with different lots of yeast, but is fairly constant in different batches prepared from the same lot of dried yeast.)

6. Precipitation at 120°C.(248°F.) before final filtration. Distribute the adjusted broth into large flasks and autoclave five minutes at 120°C.(248°F.). This causes precipitation of material that would otherwise be precipitated during the final sterilization. The precipitate is well separated from the clear supernatant liquid and the medium filters as rapidly as ordinary broth. This heating usually causes a drop in pH from 8.0 to 7.9.

7. Final sterilization. Distribute the filtered broth in the desired containers and sterilize 12 to 15 minutes at 120°C.(248°F.). This usually causes the pH to drop to 7.

II. PREPARATION OF AGAR MEDIUM WITH "5% YEAST" BROTH AS BASE

1. Preliminary softening of agar. Add 250 grams agar to about two liters water and let it soak until time for its addition to the medium.

2. Preparation of yeast broth base. Proceed as in Steps 1, 2, and 3 described under I. (Use 10 liters water as the decrease in volume will compensate for the water added to the agar.)

3. Adjust volume of broth, if decrease in volume after filtration has reduced it lower than 7.5 liters.

4. Adjustment of pH. Raise pH to about 7.4 to 7.5. Add 150 grams phosphate dissolved in about 500 ml. water as in Step 5 in I. This should bring reaction to at least pH 8.1, and if final pH of 7.8 is desired, the reaction should be readjusted if it is now below pH 8.0.

5. Addition of agar. Add agar softened by previous soaking in Step 1.

6. Solution of agar and precipitation before final sterilization. Autoclave for 15 minutes at 120°C. (248°F.) instead of the five minutes employed in Step 6 of I, in order to dissolve the agar. Filter through cotton and test pH which should now be pH 7.8 to 7.9.

7. Final sterilization. As in analogous step in I.

III. PREPARATION OF "12% YEAST" BROTH

This medium is prepared by essentially the same procedure as described in I for "5% yeast" broth with the exception that the amount of dried yeast is increased to 120 grams per liter. The additional amount of yeast makes the preparation of this medium much more time consuming, for filtration which is rapid with the "5%" medium is slow with the "12%" medium.

IV. PREPARATION OF AGAR MEDIUM WITH "12% YEAST" BROTH AS BASE

Agar medium may be prepared by the addition of 2.5 per cent agar to the "12% yeast" broth.

Savage and Hunwicke's²¹⁷ Yeast-Water Medium. One hundred gm. of ordinary brewers' yeast and one liter of distilled water are well mixed and autoclaved in a flask at 120°C. (248°F.) for 10 minutes. After being filtered twice through chardin filter paper, the yeast water is usually sufficiently clear for use. One per cent of sucrose is then dissolved in it, and litmus solution added. The medium is tubed in double tubes in amounts of about 10 ml. The tubes are autoclaved to sterilize, as any partial alteration of the sucrose would not matter. Yeasts grow well in this medium.

Friedmann's²¹⁸ Nutrient Medium From Yeasts. Ten grams of dried yeast and five grams of sodium chloride are allowed to stand with one liter of water for three-quarters of an hour at room temperature and then boiled for one hour in a steam chamber. To the hot, turbid liquid are added five ml. of colloidal iron solution (liquor ferri oxy-chlorati) with stirring, the whole is heated again for 20 minutes and filtered through a double pleated filter, the filtrate being returned to the filter until it runs through clear. The liquor is then sterilized by heating, and serves as well as meat extract for the preparation of nutrient agar, fuchsin agar, litmus milk agar, or Löffler's blood serum.

Reiter's²¹⁹ Nutrient Medium From Yeast. Washed brewers' yeast is converted, by careful drying, into a light powder which can be kept indefinitely. On account of its hygroscopic character it is best preserved in closed glass vessels. For the preparation of nutrient broth, one part of this dried yeast is mixed with 100 parts of water, allowed to stand for an hour and then heated for another hour in an autoclave. The liquid is then filtered, first through cotton wool and afterwards through filter paper. The extract thus obtained constitutes an excellent substitute for meat broth and can be used for the preparation of agar media. The use of a larger proportion of dried yeast is not advisable, since the growth of colonies is not improved thereby, and their characteristic features become less conspicuous. Addition of peptone to yeast extract is unnecessary.

Hall and Lothrop's¹⁸² Clarified Malt-Extract Medium for Yeasts and Molds. This is a clear medium compounded as follows:

Dry malt extract (Difco).....	100 gm.
Distilled water.....	1,000 ml.

Dissolve powdered malt extract in the water by heating in an Arnold sterilizer, or on the water bath. Adjust to pH 4.7 and cool to 50°C. Add slowly 100 ml. of a five per

217. Savage and Hunwicke. 1923. *Gt. Brit. Food Invest. Bd., Spec. Rpt. No. 13.*

218. Friedmann. 1918. *München. Med. Wchnschr.* 65, 76.

219. Reiter. 1918. *Deut. Med. Wchnschr.* 43, 1201-1202.

cent suspension of Bentonite (colloidal clay) and mix vigorously. Hold at 50 to 75°C. (122 to 167°F.) for 30 minutes, then filter through a fluted paper filter until clear. Heat the filtrate in the autoclave 10 minutes at 15 pounds pressure, and filter through paper to remove any precipitate formed. Distribute into tubes and flasks. For a plating medium, dissolve by heating two per cent agar-agar in the clarified broth and filter if necessary through cotton and cheesecloth. To avoid further precipitation sterilize at 10 pounds pressure for 15 minutes and cool promptly. (Bacto Malt Extract Broth can now be obtained in convenient dehydrated form and may be substituted for the above medium.)

Devereux's²²⁰ Yeast-Extract Media for Bacterial Examination of Milk. The following media supported luxuriant growth of *Lactobacillus acidophilus* and *Lactobacillus bulgaricus*. The medium had the following composition:

Yeast extract (Difco).....	5 gm.
Peptonized milk (Difco).....	10 gm.
Salt.....	5 gm.
Dextrose.....	10 gm.
Water.....	1,000 ml.

Adjust the pH to 7.0 and autoclave for 15 minutes at 15 pounds. For a solid medium add 15 grams of washed agar to each liter of the above medium.

MEDIA FOR CULTIVATION OF YEASTS

These must be more acid than media for bacteria. In addition to those mentioned below, a few others are described in Chapter 8.

Sabouraud's²²¹ Agar Medium for Yeasts. This medium has the following composition:

Agar.....	20 gm.
Peptone.....	20 gm.
Glucose.....	40 gm.
Water.....	1,000 ml.

The ingredients should be mixed in the usual manner. The reaction should be adjusted to about pH 4.0 or lower. Care must be used in sterilization else it may not solidify.

Beer Wort (Eyre²²²). 1. Weigh out 250 gm. malt and put into a flask.

2. Add 1,000 ml. distilled water heated to 70°C.(158°F.) and close flask with rubber stopper.

3. Place the mixture in a water bath at 60°C.(140°F.) and allow the mixture to stand for one hour.

4. Strain through cheesecloth into clean flask and heat in an Arnold for 30 minutes.

5. Filter through paper.

6. Tube in 10-ml. quantities and sterilize in an Arnold.

Reddish²²³ has proposed the following substitute for brewery wort:

"One hundred grams of dry extract of malt are dissolved in 900 ml. of distilled water. This is then made up to 8° Kaiser (saccharometer) by adding about 100 ml. of distilled water. The reaction is then adjusted to 1.5 per cent acid. After cooking in the autoclave for 15 minutes at 15 pounds pressure, the medium is filtered through filter paper and sterilized. It should not be sterilized at the same temperature and pressure at which it was cooked for a precipitate will come down. Agar may be added to this solution to give a solid medium."

"Near Beer Agar Medium for Yeasts. Secure a bottle of any of the so-called "near beers" and pour the contents into a beaker; boil for several minutes in order to rid the fluid of carbon dioxide. Dilute 400 ml. of the "near beer" with 600 ml. of distilled water. Add 1.5 per cent of agar, dissolve, tube, and sterilize in the usual

223. Reddish. 1919. Abs. Bact. 3, 6.

manner. In order to prepare a liquid culture medium, proceed as directed in the paragraph above but do not add the agar.

Lactic Acid-Dextrose Agar for Yeasts. Prepare dextrose agar in the usual manner and pour into Erlenmeyer flasks in quantities of 100 ml. or 50 ml. Plug and sterilize. When ready to use the medium, melt a flask of the dextrose agar containing 100 ml. and, with a sterile pipette, add four ml. of the sterilized five per cent solution of lactic acid. Shake, to thoroughly mix, and distribute into plugged tubes, plates, flasks, etc.

Savage and Hunwicke's²¹⁷ Sucrose-Mineral Medium for Yeasts. While this medium was devised for isolating yeasts from cans of condensed milk, it would probably be useful in other fields.

Ammonium sulfate.....	4.7 gm.
Dihydrogen potassium sulfate.....	0.75 gm.
Magnesium sulfate.....	0.10 gm.
Sucrose.....	50.00 gm.
Water.....	1,000.00 ml.

Sterilize in double tubes.

Weldin's²²³ Medium for Yeasts. Weldin used the following medium for yeasts: Malt extract (Difco) 15 gm., K_2HPO_4 one gm., NH_4Cl one gm., distilled water 1,000 ml. The medium is adjusted with citric acid to pH 5.4 to 5.6. A solid medium on which yeasts grow vigorously is malt extract (Difco) 15 gm., K_2HPO_4 three gm., NH_4Cl one gm., agar 20 gm. (amount of agar, however, optional). The medium is adjusted with citric acid to pH 5.4 to 5.6.

Gorodkova's²²⁵ Medium for Determining the Presence of Ascospores in Yeasts. This medium was proposed for showing the presence of ascospores in yeasts. It has the following composition:

Distilled water.....	100.0 gm.
Agar.....	1.0 gm.
Meat extract.....	1.0 gm.
Sodium chloride.....	0.5 gm.
Glucose.....	0.25 gm.

This medium may be used as slants in test tubes or poured into Petri dishes. It was said to stimulate the formation of ascospores in three or four days.

Maneval's²²⁶ Modification of Gorodkova's Medium:

Distilled water.....	100.0 ml.
Liebig's meat extract.....	0.3 gm.
Sodium chloride.....	0.5 gm.
Dextrose.....	0.25 gm.
Agar.....	1.5 to 2.0 gm.

Sterilize at 15 pounds pressure.

Mrak, Phaff, and Douglas's²²⁷ Medium for Ascospore Formation in Yeasts and Other Fungi. Grind equal amounts of washed, but unpeeled, carrots, beets, cucumbers, and potatoes and add an equal weight of water. Autoclave the mixture at 10 pounds pressure for 10 minutes after which the solid portion should be strained off with cheesecloth and pressure. The pH of the extract is usually about 5.7 and the Balling degree about 4. Two per cent of agar is added to the extract, which is dissolved by heating. Distribute as slants and sterilize at 15 pounds pressure for 15 minutes. Mrak and his colleagues obtained good sporulation on this medium within seven days.

227. Mrak, Phaff, and Douglas. 1942. Science 96, 432.

Shutt's²²⁸ Malt Extract-Agar Medium for Yeast and Mold Analysis of Butter. Shutt used the following medium for yeast and mold analysis of butter:

Malt extract (Panomalt).....	45 gm.
Agar, market.....	15 gm.
Water, tap.....	1,000 ml.

Dissolve, filter, and dispense into 250 ml. lots and sterilize. Before pouring plates, acidify the melted medium by adding 10 ml. of a sterile five-per cent solution of lactic acid to 250 ml. of medium. The final reaction should be approximately pH 3.5.

Hertz and Levine's²²⁹ Fungistatic Medium for Enumeration of Yeasts. This medium consists of malt extract agar into which is incorporated 100 parts per million of diphenyl after the melted basal medium has been cooled to between 50°C.(122°F.) and 60°C.(140°F.). The basal medium consists of:

Malt extract (Difco).....	20 gm.
Peptone (Difco).....	1 gm.
Ammonium chloride.....	1 gm.
K ₂ HPO ₄	1 gm.
Agar.....	20 gm.
Water.....	1,000 ml.

Lactic acid to bring reaction to pH 4.5 to 4.7.
(7.0 ml. N/1 lactic acid solution for control medium.)

Dissolve the ingredients in the water and dispense in 100-ml. portions in bottles and sterilize. This medium without fungistatic substances may be used as control medium.

Linden's¹⁸² Clarified Malt-Extract Medium for Yeasts and Molds. The medium most extensively used in the Beer Wort, or Malt Extract Medium, suggested by Eyre.²²² Various modifications exhibit the same difficulty as this medium, that is, formation of precipitates during sterilization. Recently, Hall and Lothrop¹³² devised a satisfactory yeast medium, utilizing the clarifying principle of a five-per cent suspension of Bentonite on honey. This clarification technic has been applied to malt extract media with favorable results. The directions follow:

Dry malt extract (Difco).....	100 gm.
Distilled water.....	1,000 ml.

Dissolve the powdered malt extract in the water by heating in an Arnold sterilizer, or on the water bath. Adjust to pH 4.7 and cool to 50°C. Add slowly 100 ml. of a five-per cent suspension of Bentonite (colloidal clay) and mix vigorously. Hold at 50 to 75°C.(122 to 167°F.) for 30 minutes, then filter through a fluted paper filter until clear. Heat the filtrate in the autoclave 10 minutes at 15 pounds pressure, and filter through paper to remove any precipitate formed. Distribute into tubes or flasks. For a plating medium, dissolve by heating, two per cent agar-agar in the clarified broth, and filter if necessary through cotton and cheesecloth. To avoid further precipitation sterilize at 10 pounds pressure for 15 minutes and cool promptly.
